Since its founding, NASA has been dedicated to the advancement of aeronautics and space science. The NASA Scientific and Technical Information (STI) program plays a key part in helping NASA maintain this important role.

The NASA STI Program operates under the auspices of the Agency Chief Information Officer. It collects, organizes, provides for archiving, and disseminates NASA's STI. The NASA STI program provides access to the NASA Aeronautics and Space Database and its public interface, the NASA Technical Reports Server, thus providing one of the largest collections of aeronautical and space science STI in the world. Results are published in both non-NASA channels and by NASA in the NASA STI Report Series, which includes the following report types:

- **TECHNICAL PUBLICATION.** Reports of completed research or a major significant phase of research that present the results of NASA programs and include extensive data or theoretical analysis. Includes compilations of significant scientific and technical data and information deemed to be of continuing reference value. NASA counterpart of peer-reviewed formal professional papers but has less stringent limitations on manuscript length and extent of graphic presentations.

- **TECHNICAL MEMORANDUM.** Scientific and technical findings that are preliminary or of specialized interest, e.g., quick release reports, working papers, and bibliographies that contain minimal annotation. Does not contain extensive analysis.

- **CONTRACTOR REPORT.** Scientific and technical findings by NASA-sponsored contractors and grantees.

- **CONFERENCE PUBLICATION.** Collected papers from scientific and technical conferences, symposia, seminars, or other meetings sponsored or cosponsored by NASA.

- **SPECIAL PUBLICATION.** Scientific, technical, or historical information from NASA programs, projects, and missions, often concerned with subjects having substantial public interest.

- **TECHNICAL TRANSLATION.** English-language translations of foreign scientific and technical material pertinent to NASA's mission.

Specialized services also include creating custom thesauri, building customized databases, organizing and publishing research results.

Measuring Crack Length in Coarse Grain Ceramics

Jonathan A. Salem and Louis J. Ghosn
National Aeronautics and Space Administration
Glenn Research Center
Cleveland, Ohio 44135

Abstract
Due to a coarse grain structure, crack lengths in precracked spinel specimens could not be measured optically, so the crack lengths and fracture toughness were estimated by strain gage measurements. An expression was developed via finite element analysis to correlate the measured strain with crack length in four-point flexure. The fracture toughness estimated by the strain gaged samples and another standardized method were in agreement.

Introduction
Three techniques for measuring the fracture toughness of ceramics were standardized by the American Society for Testing and Materials (ASTM) (Refs. 1 to 3): the chevron-notched beam (VB), the single edged precracked beam (SEPB), and the surface crack in flexure. One issue concerning the techniques is the measurement of crack length, which has been identified as a major source of error in fatigue and fracture testing of metallic materials (Ref. 4). In ceramics, crack length measurement can be particularly difficult for a number of reasons: the small specimens typically used; the semi-opaque nature of many glass-based ceramics; the lack of plastic deformation at the crack tip which results in poor definition of the crack front; and high elastic modulus and low fracture toughness that result in small crack opening displacements. Ceramics with coarse grain structure, such as ZnSe, alumina and MgAlO₄ (spinel), present an additional difficulty because the crack front is difficult to delineate from the grain boundaries.

A simple and sensitive technique that can be used to estimate crack length and extension in SEPB specimens is the back-face strain gage (BFSG), as illustrated in Figure 1. BFS was previously used with metallic compact-tension specimens (Ref. 5), and in fine gain, opaque ceramics (Ref. 6). An additional benefit of strain gaging specimens is the ability to easily monitor the stability of the test, which is a requirement for the chevron-notch method.

This communication illustrates how BFS was employed to measure crack length and fracture toughness in a transparent, coarse grain spinel.

Finite Element Analysis
A two dimensional, plane strain finite element analysis (FEA) was performed to determine the BFS as a function of normalized crack length \((a/W)\) for the four-point flexure specimen. The FEA results from several specimen heights were combined by writing the BFS as:

\[
\varepsilon_{BF} = \varepsilon_N \frac{P(S_o - S_i)}{EBW^2}
\]

where \(P\) is the applied force, \(S_i\) and \(S_o\) are the inner and outer spans, \(E\) is the elastic modulus, \(B\) is the thickness, \(W\) is the height, \(a\) is the crack length, and \(\varepsilon_N\) is the normalized strain taken as a function of normalized crack length. The normalized crack length as a function of absolute normalized BFS as determined from the FEA is shown in Figure 2. For \(a/W = 0\), \(\varepsilon_N = 3/2\), which corresponds to that of an uncrack beam. The BFS is more sensitive to crack length changes for normalized lengths greater than \(a/W = 0.3\).
The FEA BFS results were fit via least squares regression:

\[
a/W = \frac{-0.0732199 + 0.7643304 \ln \varepsilon_N - 1.4386992 (\ln \varepsilon_N)^2}{1 - 2.1294083 \ln \varepsilon_N - 0.8732785 (\ln \varepsilon_N)^2 - 0.0197908 (\ln \varepsilon_N)^3}
\]  

with the strain taken in absolute terms. Equation (2) resulted in correlation better than \( r^2 = 0.999 \).

Equation (2) requires knowledge of \( \varepsilon_N \) to determine \( a/W \). This can be estimated from the compliance observed \( (\varepsilon/P) \) prior to stable crack extension, as shown in Figure 3. Then the mode I stress intensity factor at any point during the test can be estimated from Equation (3), where \( F(a/W) \) is the appropriate stress intensity factor coefficient (Ref. 3):

\[
K_I = \frac{P(S_o - S_i)}{BW^{3/2}} F(a/W).
\]  

For fracture toughness measurements \( (K_{I Britt}) \), the maximum load observed and the initial crack length are employed in Equation (3).
Experimental Application

During recent testing of a transparent spinel (MgAlO4), crack length could not be measured to the operational requirements of ASTM C1421. The coarse structure and poor crack front definition, even with indicial illumination, can be seen in Figure 4. Thus BFS was employed to estimate the effective crack length and thereby estimate the fracture toughness $K_{pfb}$.

Precracking of 3.0 by 4.0 mm² cross-sections was performed using a 4 mm bridge span with three, 5 kg Vickers indentations. A 1 mm strain gage was employed, and the precracked beams loaded between 20 and 40 mm spans at a rate of 0.2 mm/min in air or dry nitrogen. Chevron-notched tests were also conducted using the same spans and a 1 mm strain gage. Example $P$-BFS curves are shown in Figure 3.
for SEPB and VB tests, and the results are summarized in Table 1. Good agreement occurs between the techniques. The elastic constants in Table 1 were determined in accordance with ASTM C1259 (Ref. 7).

**Conclusion**

Back-face strain is a simple, inexpensive method for monitoring crack length in ceramic flexure specimens when the usual optical techniques are inadequate. The fracture toughness of a transparent spinel, as measured with BFS applied to the SEPB specimen, was comparable to that measured using the chevron-notch in flexure. Monitoring BFS in chevron-notched specimens is also very useful, as the stability is clearly determined.
