July 2011
Since its founding, NASA has been dedicated to the advancement of aeronautics and space science. The NASA Scientific and Technical Information (STI) program plays a key part in helping NASA maintain this important role.

The NASA STI Program operates under the auspices of the Agency Chief Information Officer. It collects, organizes, provides for archiving, and disseminates NASA's STI. The NASA STI program provides access to the NASA Aeronautics and Space Database and its public interface, the NASA Technical Reports Server, thus providing one of the largest collections of aeronautical and space science STI in the world.

Results are published in both non-NASA channels and by NASA in the NASA STI Report Series, which includes the following report types:

- **TECHNICAL PUBLICATION.** Reports of completed research or a major significant phase of research that present the results of NASA programs and include extensive data or theoretical analysis. Includes compilations of significant scientific and technical data and information deemed to be of continuing reference value. NASA counterpart of peer-reviewed formal professional papers but has less stringent limitations on manuscript length and extent of graphic presentations.

- **TECHNICAL MEMORANDUM.** Scientific and technical findings that are preliminary or of specialized interest, e.g., quick release reports, working papers, and bibliographies that contain minimal annotation. Does not contain extensive analysis.

- **CONTRACTOR REPORT.** Scientific and technical findings by NASA-sponsored contractors and grantees.

- **CONFERENCE PUBLICATION.** Collected papers from scientific and technical conferences, symposia, seminars, or other meetings sponsored or cosponsored by NASA.

- **SPECIAL PUBLICATION.** Scientific, technical, or historical information from NASA programs, projects, and missions, often concerned with subjects having substantial public interest.

- **TECHNICAL TRANSLATION.** English-language translations of foreign scientific and technical material pertinent to NASA's mission.

Specialized services also include creating custom thesauri, building customized databases, organizing and publishing research results.

For more information about the NASA STI program, see the following:

- Access the NASA STI program home page at [http://www.sti.nasa.gov](http://www.sti.nasa.gov)
- E-mail your question via the Internet to help@sti.nasa.gov
- Fax your question to the NASA STI Help Desk at 443–757–5803
- Telephone the NASA STI Help Desk at 443–757–5802

Abstract

We address requirements for laboratory testing of Dielectric Barrier Discharge (DBD) plasma actuators for active flow control in air vehicles and jet engines. The performance of these actuators depends on the gas discharge properties, which in turn, depend on the pressure and temperature. When performing a characterization of actuators in a laboratory chamber without external flow, the test-chamber pressure and temperature must be set to the flight pressure and temperature at the actuator location. It is desirable to perform the tests at room temperature because it is technically challenging to simultaneously set pressure and high temperature in a chamber. We make the assumption that the plasma discharge depends only on the gas density, and ignore all other temperature effects. The tests can then be performed at room temperature with chamber pressure set to match the density in flight conditions. We calculated the needed test-chamber pressures for altitude flight of an air vehicle, and for jet engines at sea-level takeoff and altitude cruise conditions. For air vehicles, we show several examples of the chamber pressure dependence on flight at altitudes up to 65,000 ft. For jet engines, we first generated the needed data by constructing generic models of four engine thrust classes; 300-, 150-, and 50-passenger (PAX) aircraft engines, and a military jet-fighter engine. We calculated the static and total pressure, temperature, and density distributions along the engine for sea-level takeoff and for altitude cruise conditions, and we present the corresponding test-chamber pressures. The range is from 12.4 to 0.03 atm, depending on the altitude, the engine class, and the placement of the actuator. For example, if a DBD plasma actuator is placed at the compressor exit of a 300 PAX engine, it must be tested at 12.4 atm for takeoff, and at 6 atm for cruise. If it is placed at the low-pressure turbine exit, the test pressures are 0.5 and 0.2 atm, respectively. The engine models are non-proprietary and the data can be used for evaluation requirements of other types of actuators and for other purposes. We also included the distributions of unit Reynolds number, Mach number and velocity along the engines.

Nomenclature

\[ H, h \quad \text{Altitude} \]
\[ M \quad \text{Mach number} \]
\[ P \quad \text{Static pressure} \]
\[ R \quad \text{Gas constant} \]
\[ \textit{Rey} \quad \text{Reynolds number} \]
\[ T \quad \text{Static temperature} \]
\[ V \quad \text{Velocity} \]
\[ X \quad \text{Axial distance along the engine} \]
\[ \rho \quad \text{Density} \]

Subscripts:
\[ c \quad \text{Conditions in chamber} \]
\[ \infty \quad \text{Freestream conditions} \]
\[ \text{atm} \quad \text{Atmospheric conditions} \]
Acronyms:

HPC    High Pressure Compressor
HPT    High Pressure Turbine
LPC    Low Pressure Compressor
LPT    Low Pressure Turbine
PAX    Passengers

I. Introduction

There is a strong interest in active flow control techniques for applications in air vehicles as well as in jet engines; for example, to eliminate flow separation, improve efficiency or reduce noise (Ref. 1). Dielectric Barrier Discharge (DBD) plasma actuators have been proposed for active flow control of various flows, and the technology has been an active research area in the last decade.

The main active flow control technique in aerodynamics is based on injection of small jets in a steady or unsteady manner into the flow. The small input creates a large global effect that provides the desired flow improvement. DBD plasma actuators create a wall-jet by purely electronic means. The jet can be operated in steady mode, or in unsteady mode (by pulsing or modulating), and it can be used for active flow control, similar to any pneumatically- or mechanically-generated jet.

A DBD actuator is shown in Figure 1. The actuator consists of a pair of thin conducting electrodes separated by a dielectric. Usually there is one exposed electrode and one covered electrode and the electrodes are offset. Typically, at atmospheric conditions, a high voltage (1 to 40 kV RMS), high frequency (1 to 20 kHz) signal is applied to the electrodes, creating localized weakly ionized gas plasma discharge on the surface near the edge of the exposed electrode. A typical discharge is shown in Figure 2.

The jet is generated in the plasma region via the electrohydrodynamic effect, a process of collisions between ions and neutral molecules in the plasma. The actuator construction is very simple, but the physical mechanisms involved are quite complex and include interactions among electrical fields, electrons, positively and negatively charged species, the electrodes, and the dielectric surface (Refs. 2 to 4). Gas is drawn from the surroundings to form a thin wall jet that is roughly parallel to the surface and directed away from the exposed electrode edge in the direction of the covered electrode, as visualized by experiments and computation (Refs. 5 to 7). There is slight heating involved, but its effect on the jet is negligible. Other types of plasma-based flow control devices that generate localized intense heating (Ref. 8) are not included in the scope of devices addressed in this paper. More detailed information and references on DBD actuators and their application for aerodynamic flow control can be found in several review articles (Refs. 9 to 12).

The advantages of DBD actuators are that they are surface-mounted, fully electronic, low power, high frequency-band devices. There are no moving parts, tubes, ducts or surface holes. Flexible operation is possible by controlling the input voltage and waveforms. DBD plasma actuators are particularly attractive for gas turbine and turbomachinery applications; they are thin, surface mounted, and do not require internal volumes or passages. Their construction can be made suitable for a high-temperature environment by choosing high-temperature alloys for the electrodes and temperature-resistant ceramic materials for the dielectric. They can easily be integrated with futuristic engine components to be made of ceramics and composites.

The majority of the research in the DBD actuators area has been focused on applications in external flows, particularly for wings and airframes, rather than on propulsion. But there have been important efforts directed at turbomachinery applications. There have been several successful experimental demonstrations of active flow control with DBD plasma actuators to eliminate low Reynolds number separation in Low-Pressure Turbine flows (Refs. 13 to 16), and to reduce effects of turbine tip leakage (Refs. 17 to 20). Those experiments were performed in wind tunnels or linear cascades at room temperature.

DBD actuators need to be tested in actual flight conditions in order to be used as flow control devices in practical applications. Only a few flight tests were performed on air vehicles; on a small remotely controlled airship (Refs. 21 and 22), a full-size piloted glider (Ref. 23), and a small UAV (Ref. 24), but no tests have been performed in jet engines. Before performing flight tests, the actuators must be tested in the laboratory. The aerodynamic performance of the actuators must be characterized to prove that they have sufficient authority at the flow conditions at the location of their placement in the air vehicle or jet engine. In addition, the electrical performance, particularly the power consumption of the actuators, must be quantified, as it is needed for design of power supplies and for cost-benefit analysis of the flow control technology. This paper addresses the test conditions needed to characterize the actuators in the laboratory.
The basic characterization in the laboratory is performed without external flow. The aerodynamic performance is characterized by measuring the velocity profile of the wall jet and/or the thrust generated by the actuator. The electrical performance is characterized by measuring the current, voltage, and power. Most of the tests to date have been performed at room temperature and atmospheric conditions, but in order to simulate flight conditions the actuator must be placed in a chamber with controlled temperature and pressure representative of the flow conditions in flight. A small number of tests are reported in the literature in chambers at room temperature and sub-atmospheric conditions, with some conflicting results (Refs. 25 through 32). Tests at atmospheric altitude conditions have been performed in an environmental chamber (Ref. 33), where temperature and pressure were varied simultaneously. These tests were primarily motivated by their applicability to external aerodynamics. Tests at above-atmospheric pressures at room temperature were reported in References 34 and 35, and were mainly motivated by their application to internal aerodynamics.

The actuator performance must be tested in conditions that simulate the operating conditions in flight, at the location where the actuator is placed. The applications in the jet engine are particularly challenging because of the high temperatures and high pressure ratios in several engine components. It is challenging to simultaneously set pressure and high temperature in a test chamber, and therefore it is desirable to find a simpler approach to eliminate this technical complication. The question that arises is how to simulate the conditions in an operating jet engine in order to test the actuators properly. Because the principle of operation of DBD actuators depends on electrical discharges and on the associated force generation mechanisms, the performance of the actuator will be affected by the pressure, temperature and properties of the gas. It is assumed that for the range of temperatures in atmospheric flight and in the jet engine, the gas density alone is the significant gas property influencing the performance of the actuator. Therefore, the flight conditions can be simulated by matching the density in the laboratory. It is a simple idea that has not been proposed before.

The outline of this paper is as follows. After addressing a relatively simple case of an air vehicle flying at altitude, attention is focused on the jet engine applications. First, information is provided on pressure, temperature, density, unit Reynolds number, Mach number, and velocity distribution along the flow-path of four thrust classes of jet engines. This information is derived from non-proprietary engine models used in system analysis studies done by NASA. These models include cycle, flow path and sizing. Then, by setting the test-chamber pressure at room temperature, the density in the chamber is matched to the in-flight operating conditions. The range of the needed chamber pressures was calculated by matching the densities and using the ideal gas law. It depends on the placement of the actuator, and the results are presented for the four engine classes at takeoff and cruise conditions. This information is useful as a guideline for testing requirements of DBD plasma actuators at engine flight conditions. The engine information documented here, which is often hard to find in publicly available sources, is useful for evaluation of other types of actuators as well as for other purposes.

II. Jet Engine Data Source—Engine Models

The engine models used in this study were developed based on information available in the open literature and from empirical estimates. Cycle analysis was performed with the Numerical Propulsion Simulation System (NPSS) code (Refs. 36 and 37), providing performance parameters such as thrust, component pressure ratios, and velocities, temperatures, and pressures at each engine station. Aeromechanical analysis and estimates of engine and component weights were calculated using the Weight Analysis of Turbine Engines (WATE) code (Ref. 38), which also provides a flow path schematic of the engine. Generic engine models representing four different thrust classes were developed: 300-, 150- and 50-passenger (PAX) aircraft engines, and a military jet-fighter engine. These models are a good representation of actual engines. Note that the 150 PAX model is a conceptual design of a generic geared high bypass turbofan. The primary engine parameters of thrust, weight, overall pressure ratio, and bypass ratio are listed in Table 1 and the schematic of each engine is shown in Figure 3. The axial coordinates of the components’ outflow stations are listed in Table 2.

Engine conditions were calculated at the inlet and exit flow stations of the various engine components. Data were acquired for two engine operating conditions: sea-level takeoff and altitude cruise at 35,000 ft. Data for the 50 PAX engine are also shown for an additional cruise altitude of 65,000 ft, as this type of engine is also used for high-flying air vehicles. Figures 4 through 7 show the following parameters for each engine: static and total (stagnation) pressure, temperature, and density, as well as unit Reynolds number, Mach number and velocity. Ideal gas conditions were assumed. For all data shown, the flights Mach numbers are M = 0.8 at cruise, and M = 0 at takeoff. Figure 6(d2) for the 50 PAX engine also shows unit Reynolds number for cruise Mach numbers of M = 0.5, 0.6, and 0.8 at altitude of 65,000 ft.
There are more data presented than are strictly needed for development of the subject test conditions. The reason for including the extra data is to make them available to the research community because it is hard to find non-proprietary actual engine data. The engine data presented here are unrestricted and can be used for other purposes.

III. Test Conditions for DBD Plasma Actuators

A. Assumptions

Several assumptions are used to develop the test conditions in laboratory experiments in quiescent environment (no flow) in a test-chamber:

1) The effects of temperature and pressure on plasma kinetics and chemistry are ignored. This assumption is reasonable for the range of temperatures in the jet engines, and is further discussed below.

2) The effect of temperature on the electrical properties of the actuator, particularly on the capacitance of the dielectric, is negligible. The capacitance variation was calculated in Reference 33, and was shown to be small.

3) Actuator heat generation is negligible. This assumption is based on experimental observations for the range of power and voltages applied to conventional DBD plasma actuators.

4) Gas thermodynamic properties are constant (except in the engine model data calculations).

5) Gas composition effects are ignored. There is a small effect of the composition of the atmosphere variation with altitude mainly due to variation of the oxygen/nitrogen ratio (Ref. 32). Effects due to the presence of combustion products in the areas of the engine downstream of the combustors, and effects of humidity are assumed to be insignificant.

6) Gas viscosity is assumed not to affect the actuator performance. In principle, viscosity dependence on temperature can affect the development of the wall-jet generated by the actuator. (Sutherland's law was used in calculating the unit Reynolds number in the engine models.)

The main assumption is that the gas density is the only parameter that governs the physical process of the wall-jet generation by the plasma discharge. A process of collisions between ions and neutral molecules creates the forces that result in the wall-jet. The collisions are governed by the mean-free-path and the number of molecules in a unit volume. Therefore, with the assumptions listed above, the gas density in laboratory tests should be set to be equal to the density at the application flight conditions.

Assessment of the validity of these assumptions and possible subsequent refinements are a subject for future work. With these assumptions, the main factor affecting the jet generation dependence on pressure and temperature is captured by considering only the density.

Validation of the assumption that temperature affects only the density is not trivial. It is known that some of the reactions between different charged molecules and electrons in the plasma are temperature dependent. Usually the dependence is weak, except for the temperature dependence of electron attachment processes, which can be significant above 1800 °R (1000 K). It seems that the only practical approach to assess the full effect of temperature and pressure on the momentum transferred to the fluid is to use numerical simulation of the DBD plasma actuator at different temperatures and pressures. This simulation is challenging and is planned to be performed in the future. The authors are not aware of any reported work on this topic.

The assumption that the temperature affects only the density is very reasonable for temperatures under 1800 °R (1000 K). The open question is whether it is significant at higher temperature levels. If it turns out to have a large effect, it is expected to affect the calculated test conditions only for jet engine applications in the combustion chamber and the high-pressure turbine, which are at temperatures higher than 1800 °R, as seen from Figures 4 through 7.

B. Test-chamber pressure

The chamber pressure and temperature to yield the same density as in flight are calculated as follows:

The gas density in the laboratory test chamber should be the same as the density at the application flight conditions,

\[ \rho_c = \rho \]  

\( (1) \)

where subscript \( c \) indicates conditions in the chamber.

Assuming an ideal gas of a fixed species, and therefore with constant \( R \),
\[ \rho = \frac{P}{RT} \]  \hspace{1cm} (2)

the following relationship is obtained

\[ P_c = \frac{P}{T/T_c} \]  \hspace{1cm} (3)

where

\[ P_c, T_c, \rho_c \] – Laboratory chamber pressure, temperature, and density.

\[ P, T, \rho \] – Static pressure, temperature, and density at flight conditions

C. Test-chamber pressures for air vehicles

The chamber pressures \( P_c \) were calculated first for the case of an air vehicle (Figure 8). An air vehicle is flying at altitude \( h \) at Mach number \( M_\infty \). The atmospheric pressure at altitude \( h \) is \( P_{\text{atm}}(h) \) and the temperature is \( T_{\text{atm}}(h) \), and are given by Standard Atmosphere tables. The local Mach number at the actuator location is \( M \), which can be larger or smaller than \( M_\infty \), depending on the flow development on the body, as determined by its geometry and flight conditions. We assume isentropic flow without shock waves. Using isentropic relationships at the freestream and at the actuator placement location with common stagnation conditions, and taking the atmospheric conditions at altitude \( h \) as the static conditions, we obtain:

\[ P_c = T_c \frac{P_{\text{atm}}(h)}{T_{\text{atm}}(h)} \frac{f(M)}{f(M_\infty)} \]  \hspace{1cm} (4)

where

\[ f(M) = \left[ 1 + \frac{\gamma - 1}{2} M^2 \right]^{-\frac{1}{\gamma - 1}} \]  \hspace{1cm} (5)

The chamber pressures for the following special cases are:

1) Actuator placed on a stationary vehicle at altitude \( h \): \( M_\infty = 0, \) \( M = 0 \)

Therefore \( f(M_\infty) = 1, \) \( f(M) = 1, \) and we obtain from Eq. (4),

\[ P_c = T_c \frac{P_{\text{atm}}(h)}{T_{\text{atm}}(h)} \]  \hspace{1cm} (6)

This result is expected, as the static density on a stationary vehicle is the same at the atmosphere density.

2) Actuator placed on a flat plate at altitude \( h \) at zero angle of attack: \( M_\infty = M \)

We obtain from Eq. (4) the same relationship,

\[ P_c = T_c \frac{P_{\text{atm}}(h)}{T_{\text{atm}}(h)} \]

This result is also expected, as the static conditions are the same as the atmospheric conditions.

3) Actuator placed at the stagnation point (as is common for flow control of airfoil leading edge stall): \( M = 0, \) and we obtain from Eq. (4)
The chamber pressure $P_c$ is shown in Figure 8 as a function of altitude for the first two cases (Eq. (6)), and for flight Mach numbers $M_{\infty} = 0.5$, with local Mach numbers of $M = 0$ (stagnation point) and $M = 0.8$ (Eq. (4)). A curve for $M_{\infty} = 1$ with local Mach number of $M = 0$ (stagnation point), representing an extreme case, is also shown. An example of a flow with shocks is also presented in Figure 8, for an actuator placed behind the oblique shock wave on a $20^\circ$ wedge at $M_{\infty} = 2$. Isentropic conditions were assumed upstream and downstream of the shock, and oblique shock relations were used to calculate the flow conditions on the wedge surface downstream of the shock.

The calculations are relatively straightforward for the shown simplified air vehicle cases. Obtaining the density at the placement location of actuators in actual configuration and flow conditions will involve obtaining data from CFD or measurement, taking into account viscosity and non-isentropic flows.

D. Test-chamber pressures for jet engines

The situation for gas turbine engine application is more complex than for air vehicles because of the turbomachinery components and the combustion processes. The test-chamber pressures needed for jet engine applications were calculated from the engine model data for the four generic engine classes. In these calculations, sea-level pressure was 14.7 psi, and sea-level temperature was 545.7 °R (29.8 °C). The latter was also taken as the value of the chamber room temperature. The results are displayed in Figure 9. Some notes on the calculations are provided in the next section.

IV. Discussion

For the air vehicle application, the chamber pressures decrease with altitude according to the variation of density with altitude and local flow conditions at the actuator location. The situation is more complex for the jet engine. The results show that the test-chamber pressure varies greatly across the different engine classes, from sub-atmospheric to above atmospheric pressures, depending on the operating conditions and location of the actuator in the engine. For example, if a DBD plasma actuator is to be placed at the inlet to the high pressure turbine for the 300 PAX engine, it must be tested at 6 atm if it is intended to operate at sea-level takeoff conditions, and at 2.9 atm if it is intended to operate at 35,000 ft cruise. If it is to be used in the exit of the high-pressure compressor duct (burner inlet), it must be tested at 12.4 atm at takeoff conditions, and at 6.2 atm at 35,000 ft cruise conditions. If it is to be used at the low-pressure turbine exit, it must be tested at 0.5 atm at takeoff, and at 0.2 atm at cruise. If the actuator is to be placed on the low-pressure turbine of the 50 PAX engine flying at 65,000 ft, its performance must be tested at a very low chamber pressure of 0.03 atm.

Note that the calculations are based on conditions at the inflow and outflow planes of the various engine components. The calculated points are connected with straight lines. Further modification is needed to account for local flow conditions inside the component. For example, in turbomachinery there are inter-row and inter-stage variations, and in inter-blade passages there is acceleration or diffusion or even shock waves that will modify the results. Those local modifications are not included in this study and are left for future work.

Note also that the results shown in Figure 9 display the chamber pressures based on total (stagnation) as well as static conditions in the engine. The reason that the results corresponding to total conditions are shown is that the total conditions are equal to static conditions at locations where the velocity is zero, corresponding to placement of the actuator at locations such as the leading edge of a turbine or compressor airfoil. As can be seen in the figure, the differences are not large.

Additional insights can be gained from the distribution of the unit Reynolds number. Usually, a low unit Reynolds number may indicate flow separation. For example, it is known that there is a tendency for flow separation on the low-pressure turbine (LPT) suction surface at altitude. Low Reynolds number locations are good candidates for implementation of active flow control. However, those locations are also characterized by low density, requiring the plasma actuator to be tested at low chamber pressures. DBD plasma actuators may suffer from loss of performance as the density is decreased (note that there are insufficient and conflicting results in the published literature on this matter). Therefore, laboratory testing is critical for establishing that the DBD actuators can perform adequately under low density conditions.
It is important to note that for research in the field of weakly ionized plasma, laboratory experiments were traditionally performed in a vacuum chamber at room temperature. It therefore became common in that field to specify the chamber pressure as an experimental parameter. This may have led to habitually considering the pressure, rather than the density, as the relevant parameter.

V. Conclusions

Data on flow conditions in four generic jet engines, representing four different thrust classes, were presented, and, because they are non-proprietary, the data are useful for various applications related to formulating test conditions of flow control devices placed in various engine components. The data were used to develop test conditions for characterization of DBD plasma actuators in a chamber at room temperature. The underlying assumption is that the performance of DBD actuators depends only on the density and that all other temperature-related effects are negligible over the temperature range existing in the jet engine. Based on this assumption, and the engine models’ data, the required test-chamber pressure for simulating in-flight engine operating conditions was calculated. The pressures vary with the location of the actuator in the engine, the type of engine, and the flight operating conditions. There is a wide spread in the pressure range, depending on the specific application. The pressure varies from 12.4 to 0.03 atm for the four engine classes’ models and the flight conditions studied. Chamber pressures needed to test actuators for flight vehicles were also shown. Unlike the engine environment, the flow conditions for testing flight vehicles can simply be calculated with data readily available from standard atmospheric tables, for any flight speed and altitude. Modifications can be added to account for local flow conditions at actuator placement. The test pressures presented rely heavily on the density matching assumption. Deviation from this assumption is not expected to be large, and it is believed that the results are correct to at least first order.

We address requirements for laboratory testing of Dielectric Barrier Discharge (DBD) plasma actuators for active flow control in air vehicles and jet engines. The performance of these actuators depends on the gas discharge properties, which in turn, depend on the pressure and temperature. When performing a characterization of actuators in a laboratory chamber without external flow, the test-chamber pressure and temperature must be set to the flight pressure and temperature at the actuator location. It is desirable to perform the tests at room temperature because it is technically challenging to simultaneously set pressure and high temperature in a chamber. We make the assumption that the plasma discharge depends only on the gas density, and ignore all other temperature effects. The tests can then be performed at room temperature with chamber pressure set to match the density in flight conditions. We calculated the needed test-chamber pressures for altitude flight of an air vehicle, and for jet engines at sea-level takeoff and altitude cruise conditions. For air vehicles, we show several examples of the chamber pressure dependence on flight at altitudes up to 65,000 ft. For jet engines, we first generated the needed data by constructing generic models of four engine thrust classes; 300-, 150-, and 50-passenger (PAX) aircraft engines, and a military jet-fighter engine. We calculated the static and total pressure, temperature, and density distributions along the engine for sea-level takeoff and for altitude cruise conditions, and we present the corresponding test-chamber pressures. The range is from 12.4 to 0.03 atm, depending on the altitude, the engine class, and the placement of the actuator. For example, if a DBD plasma actuator is placed at the compressor exit of a 300 PAX engine, it must be tested at 12.4 atm for takeoff, and at 6 atm for cruise. If it is placed at the low-pressure turbine exit, the test pressures are 0.5 and 0.2 atm, respectively. The engine models are non-proprietary and the data can be used for evaluation requirements of other types of actuators and for other purposes. We also included the distributions of unit Reynolds number, Mach number and velocity along the engines.
