Improved Indentation Test for Measuring Nonlinear Elasticity

This technique is especially useful for characterizing thermal-barrier coating materials.

John H. Glenn Research Center, Cleveland, Ohio

A cylindrical-punch indentation technique has been developed as a means of measuring the nonlinear elastic responses of materials — more specifically, for measuring the moduli of elasticity of materials in cases in which these moduli vary with applied loads. This technique offers no advantage for characterizing materials that exhibit purely linear elastic responses (constant moduli of elasticity, independent of applied loads). However, the technique offers a significant advantage for characterizing such important materials as plasma-sprayed thermal-barrier coatings, which, in cyclic loading, exhibit nonlinear elasticity with hysteresis related to compaction and sliding within their microstructures.

A specimen to be tested by the cylindrical-punch indentation technique is prepared by standard metallographic procedures. The specimen is mounted on a load-versus-displacement-measuring apparatus, which could be any of a variety of indentation-type hardness testers or other conventional mechanical testing instruments. In the indentation test, the flat end of a round cylindrical punch is pushed into the polished, flat surface of the specimen. To minimize impression creep (a time-dependent plastic deformation that could contribute a large error to the modulus data), the specimen is preconditioned by pre-indenting it at a load greater than the load to be applied during the subsequence.

These Plots of Modulus of Elasticity as a function of applied stress were calculated from displacement-vs-load data for a 127-μm-diameter flat-bottom cylindrical tungsten carbide punch against a thermal-barrier coating of plasma-sprayed ZrO₂ containing 8 weight percent of Y₂O₃ during the third loading/unloading cycle of an indentation.
Ultraviolet-Absorption Spectroscopic Biofilm Monitor

Continuous monitoring could provide early warnings of potentially harmful buildups of bacteria.

Lyndon B. Johnson Space Center, Houston, Texas

An ultraviolet-absorption spectrometer system has been developed as a prototype instrument to be used in continuous, real-time monitoring to detect the growth of biofilms. Such monitoring is desirable because biofilms are often harmful. For example, biofilms in potable-water and hydroponic systems act as both sources of pathogenic bacteria that resist biocides and as a mechanism for deterioration (including corrosion) of pipes.

Biofilms formed from several types of hazardous bacteria can thrive in both plant-growth solutions and low-nutrient media like distilled water. Biofilms can also form in condensate tanks in air-conditioning systems and in industrial heat exchangers. At present, bacteria in potable-water and plant-growth systems aboard the space shuttle (and previously on the Mir space station) are monitored by culture plate counting, which entails an incubation period of 24 to 48 hours for each sample. At present, there are no commercially available instruments for continuous monitoring of biofilms in terrestrial or spaceborne settings.

The prototype biofilm monitor includes a commercial fiber-optic-coupled ultraviolet/visible (UV/VIS) spectrometer module with charge-coupled-device (CCD) array detection that has dimensions of 6 by 6 by 2 in. (about 15 by 15 by 5 cm) and that communicates with a notebook computer via a Personal Computer Memory Card International Association (PCMCIA) interface card. The instrument includes two 4-ft (1.2-m)-long optical fibers—one for coupling light from a xenon source to a flow-cell/fiber sensor assembly, the other for coupling light from the flow-cell/fiber sensor assembly to the spectrometer module. In the flow-cell/fiber sensor assembly, the ends of the fibers are coupled into the quartz windows of the cell with small collimating lenses. The inner surfaces of the windows are in contact with the flowing water to be monitored.

In tests of the prototype biofilm monitor, biofilms were found to produce characteristic absorption spectral bands at wavelengths from 230 to 400 nm. The absorption bands obtained from biofilms grown from a single strain of Pseudomonas aeruginosa were found to differ from the absorption bands obtained from biofilms grown from a mixed bacterial population from untreated urban river water; thus, it appears possible to use instruments of this type not only to detect biofilms but also to distinguish among species of bacteria in biofilms.

This work was done by Jeffrey I. Eldridge of Glenn Research Center. Further information is contained in a TSP (see page 1).

Inquiries concerning rights for the commercial use of this invention should be addressed to NASA Glenn Research Center, Commercial Technology Office, Attn: Steve Fedor, Mail Stop 4-8, 21000 Brookpark Road, Cleveland Ohio 44135. Refer to LEW-17412.

The UV Absorption Spectroscopic Biofilm Monitor System is based on a miniature UV/VIS spectrometer with a fiber-optic input and a CCD-array detector. This instrument measures UV absorption spectra of biofilms that form on the inner surfaces of quartz windows of a flow cell.
