**Technique for Radiometer and Antenna Array Calibration — TRAAC**

This technique provides a unique and accurate method to calibrate an antenna and radiometer system.

*Marshall Space Flight Center, Alabama*

Highly sensitive receivers are used to detect minute amounts of emitted electromagnetic energy. Calibration of these receivers is vital to the accuracy of the measurements. Traditional calibration techniques depend on calibration reference internal to the receivers as reference for the calibration of the observed electromagnetic energy. Such methods can only calibrate errors in measurement introduced by the receiver only. The disadvantage of these existing methods is that they cannot account for errors introduced by devices, such as antennas, used for capturing electromagnetic radiation. This severely limits the types of antennas that can be used to make measurements with a high degree of accuracy. Complex antenna systems, such as electronically steerable antennas (also known as phased arrays), while offering potentially significant advantages, suffer from a lack of a reliable and accurate calibration technique.

The present innovation provides a method to perform an end-to-end calibration of a radio frequency (RF) receiver system comprised of an antenna and a receiver. Traditional calibration techniques cannot eliminate errors in measurement introduced by variations in antenna characteristics. The proposed invention provides a method to quantify the instantaneous, as well as long-term, variations in antenna characteristics. This technique will enable improved accuracy in measurements made using passive receiver systems and phased array systems in particular, by monitoring the performance of the antenna array by measuring the gain of the antenna electronics in real time.

The proximity of antenna elements in an array results in interaction between the electromagnetic fields radiated (or received) by the individual elements. This phenomenon is called mutual coupling. The new calibration method uses a known noise source as a calibration load to determine the instantaneous characteristics of the antenna. The noise source is emitted from one element of the antenna array and received by all the other elements due to mutual coupling. This received noise is used as a calibration standard to monitor the stability of the antenna electronics.

The proposed calibration technique makes use of five measurements. These are observations of an internal warm load, cold load (both internal to the radiometer/receiver), the scene of interest, the scene of interest with the noise source emitted from the center element of the antenna array, and a known noise source injected directly into each element of the antenna array. The noise source, coupled from the central element in the array to all other elements in a square array will be symmetric. With the noise source being emitted from the central element, the mutually coupled signal will be received on the other antenna elements, combined, and used as a calibration signal to monitor any change in the RF components (low-noise amplifiers, phase shifters, attenuators, and power combiners) in front of the radiometer. Based on these observations, a calibrated estimate of the scene can be obtained.

**Real-Time Cognitive Computing Architecture for Data Fusion in a Dynamic Environment**

This architecture can enable smart instrumentation for automotive, security, and intelligent robotics applications.

*NASA’s Jet Propulsion Laboratory, Pasadena, California*

A novel cognitive computing architecture is conceptualized for processing multiple channels of multi-modal sensory data streams simultaneously, and fusing the information in real time to generate intelligent reaction sequences. This unique architecture is capable of assimilating parallel data streams that could be analog, digital, synchronous/asynchronous, and could be programmed to act as a knowledge synthesizer and/or an “intelligent perception” processor. In this architecture, the bio-inspired models of visual pathway and olfactory receptor processing are combined as processing components, to achieve the composite function of “searching for a source of food while avoiding the predator.” The architecture is particularly suited for scene analysis from visual data and odorant
signature identification in a heterogeneous environment.

In this architecture, there are four basic blocks: input, output, processing, and storage. The input block consists of sensing devices including IR, lidar, radar, visual, chemical, and biosensors, at their various sampling data rates. Based on application scenario, selected sensory streams are sent by the input block to the subsequent "processing" block in a fully parallel fashion. Feature data is extracted from the analog/digital sensory streams and is accumulated in the storage block for enriching the "knowledge base" as a situation unfolds. The incoming raw data is not stored as is the usual approach in current computer architecture, and is reconstructed if required during the process in real time. The output block sends the output signal to various interfaces (actuating interfaces), such as other machines, humans, or RF devices. The processing block consists of several mathematical constructs including Principal Component Analysis (PCA), Independent Component Analysis (ICA), Neural Network (NN), Genetic Algorithm (GA), etc., and is controlled by a hierarchy of logical rules to enact reasoning, reconfiguring, and adapting as required when the target is changing in the dynamic environment. Therefore, the processing block can select an architecture for each particular application as needed, dynamically, and still remain compatible with a digital environment. The conceptualized architecture, capable of extracting knowledge from information and using the knowledge for reasoning, adapting, and reacting therefore qualifies as a cognitive architecture for real-time data fusion in a dynamic environment. Furthermore, its dynamic autonomous reconfigurability makes it versatile as a "general-purpose" intelligent system to accomplish the "searching for a source of food while avoiding the predator" function.

This work was done by Tuan A. Duong and Vu A. Duong of Caltech for NASA's Jet Propulsion Laboratory. Further information is contained in a TSP (see page 1).

Programmable Digital Controller
Goddard Space Flight Center, Greenbelt, Maryland

An existing three-channel analog servo loop controller has been redesigned for piezoelectric-transducer-based (PZT-based) etalon control applications to a digital servo loop controller. This change offers several improvements over the previous analog controller, including software control over proportional–integral–derivative (PID) parameters, inclusion of other data of interest such as temperature and pressure in the control laws, improved ability to compensate for PZT hysteresis and mechanical mount fluctuations, ability to provide pre-programmed scanning and stepping routines, improved user interface, expanded data acquisition, and reduced size, weight, and power.

The original analog servo controller only had the ability to correct for a single error term generated by the capacitive gap sensor. This was less than optimal when trying to return to the same gap position due to the hysteresis of the PZT motors and thermal drift in the electronics.

To overcome the limitations of the analog servo loop, it was decided that a control loop could be built around a microcontroller/central processing unit (CPU), i.e., a digital servo loop. The CPU would query various sensors such as a capacitive gap sensor or temperature sensor, among others, then based on reprogrammable control laws, provide a driving signal to a high-voltage driver that actuates the PZT motor on the etalon. The system is based on mostly COTS (commercial off-the-shelf) hardware and software.

The design is based around a new generation of direct capacitance to digital converters from Analog Devices, the AD7745. This integrated circuit (IC) allows the measurement of the capacitance of the gap capacitor at up to 90 Hz with resolutions down to 4 aF. This measurement is an absolute value whereas the previous analog design measured capacitance relative to a reference capacitor whose value had some uncertainty. The new design allows one to measure the gap directly, after calibration, thereby greatly improving overall control.

Use of CCSDS Packets Over SpaceWire to Control Hardware
Goddard Space Flight Center, Greenbelt, Maryland

For the Lunar Reconnaissance Orbiter, the Command and Data Handling subsystem consisted of several electronic hardware assemblies that were connected with SpaceWire serial links. Electronic hardware would be commanded/controlled and telemetry data was obtained using the SpaceWire links. Prior art focused on parallel data buses and other types of serial buses, which were not compatible with the SpaceWire and the core flight executive (CFE) software bus.

This innovation applies to anything that utilizes both SpaceWire networks and the CFE software. The CCSDS (Consultative Committee for Space Data Systems) packet contains predetermined values in its payload fields that electronic hardware attached at the terminus of the SpaceWire node would decode, interpret, and execute. The hardware’s interpretation of the packet data would enable the hardware to change its state/configuration (command) or generate status (telemetry).
