Lidar and Radar sensors use transmitted and received electromagnetic radiation to measure forest canopies. The combined use of lidar and radar instruments to measure forest structure attributes such as height and biomass at global scales is being considered for a future Earth Observation satellite missions. Large footprint lidar makes a direct measurement of the distance of canopy scattering elements (i.e., leaves, branches, ground) within the illuminated area and can yield accurate information about the vertical profile of the canopy within these lidar. Synthetic Aperture Radar (SAR) is known to sense the forest canopy volume, especially at longer radar wavelengths and provides image data. Methods for biomass mapping by a combination of lidar sampling and radar mapping need to be developed since neither can do the whole job individually.

In this study, several issues were investigated using aircraft borne lidar and SAR data over Howland, Maine, USA. We used a stepwise regression technique and selected the lidar derived height indices rh50 and rh75 of the Laser Vegetation Imaging Sensor (LVIS) data for predicting field measured biomass with a $R^2$ of 0.71 and RMSE of 31.33 Mg/ha. The above-ground biomass map generated from this regression model was considered to represent the true biomass of the area and used as a reference map since no better biomass map exists for the area. Random samples were taken from the biomass map and the correlation between the sampled biomass and co-located SAR signature was analyzed. The best models obtained through these analyses were used to extend the biomass estimates from lidar samples into all forested areas in the study area, which mimics a procedure that could be used for the future DESDYnI Mission. It was found that depending on the type of SAR data used (i.e., quad-pol or dual-pol) the SAR data can predict the lidar biomass samples with $R^2$ of 0.63-0.71, RMSE of 32.0-28.2 Mg/ha up to biomass levels of 200-250 Mg/ha. The mean biomass of the study area calculated from the biomass maps generated by lidar-SAR synergy was within 10% of the reference biomass map derived from LVIS data. The results from this study are preliminary, but do show the potential of the combined use of lidar samples and radar imagery for forest biomass mapping. Various issues regarding lidar/radar data synergies for biomass mapping are discussed in the paper.

Abstract

The use of lidar and radar instruments to measure forest structure attributes such as height and biomass at global scales is being considered for a future Earth Observation satellite mission, DESDynI (Deformation, Ecosystem Structure, and Dynamics of Ice). Large footprint lidar makes a direct measurement of the heights of scatterers in the illuminated footprint and can yield accurate information about the vertical profile of the canopy within lidar footprint samples. Synthetic Aperture Radar (SAR) is known to sense the canopy volume, especially at longer wavelengths and provides image data. Methods for biomass mapping by a combination of lidar sampling and radar mapping need to be developed.

In this study, several issues in this respect were investigated using aircraft borne lidar and SAR data in Howland, Maine, USA. The stepwise regression selected the height indices rh50 and rh75 of the Laser Vegetation Imaging Sensor (LVIS) data for predicting field measured biomass with a $R^2$ of 0.71 and RMSE of 31.33 Mg/ha. The above-ground biomass map generated from this regression model was considered to represent the true biomass of the area and used as a reference map since no better biomass map exists for the area. Random samples were taken from the biomass map and the correlation between the sampled biomass and co-located SAR signature was studied. The best models were used to extend the biomass from lidar samples into all forested areas in the study area, which mimics a procedure that could be used for the future DESDynI Mission. It was found that depending on the data types used (quad-pol or dual-pol) the SAR data can predict the lidar biomass samples with $R^2$ of 0.63-0.71, RMSE of 32.0-28.2 Mg/ha up to biomass levels of 200-250 Mg/ha. The mean biomass of the study area calculated from the biomass maps generated by lidar-SAR synergy was within 10% of the reference biomass map derived from LVIS data. The results from this study are preliminary, but do show the potential of the combined use of lidar samples and radar imagery for forest biomass mapping. Various issues regarding lidar/radar data synergies for biomass mapping are discussed in the paper.

1. Introduction

Above-ground biomass cannot be directly measured by any sensor from space. Land cover stratification combined with ground sampling is the traditional method to inventory the biomass of a region. Remote sensing data are playing increasingly important roles in forest biomass estimation. For example, biomass data from field measurements (e.g., FIA – Forest Inventory and Analysis plots) (Blackard, J. A., et al. 2008) and lidar (GLAS – Geoscience Laser Altimeter System) (Baccini, A., et al. 2008; Nelson et al., 2009) and image data from LANDSAT, MODIS have been used together to perform regional biomass mapping.

Large-footprint lidar systems (Blair et al., 1999) have been developed to provide high-resolution, geo-located measurements of vegetation vertical structure and ground elevations beneath dense canopies. Over the past decade, several airborne and space-borne large-footprint lidar systems have been used to make measurements of vegetation. The lidar waveform signature from large-footprint lidar instrument, such as the Scanning Lidar Imager of Canopies by Echo Recovery (SLICER) (Harding et al., 1995, 1998) and the Laser Vegetation Imaging Sensor (LVIS) (Blair et al., 1999) has been successfully used to estimate the tree height and forest above-ground biomass (Lefsky et al., 1999a, b; Dubayah and Drake, 2000; Hofton et al., 2002; Drake et al., 2002, 2003, Sun et al., 2008). The relationship between forest carbon storage and the vertical structure from lidar waveform is relatively unexplored. Further studies on the data properties, (e.g. the effects of multiple scattering and ground slope on lidar signatures) are needed to verify and improve the retrieval algorithms. One major limitation of current spaceborne lidar systems (i.e., ICESat GLAS) is the lack of imaging capabilities and the fact that they provide sparse sampling information on the forest structure.

Radar, because of its penetration capability and sensitivity to water content in vegetation, is sensitive to the forest spatial structure and standing biomass. Radar data (both polarimetric and interferometric) have been used for forest biomass estimation (Ranson and Sun, 1996, Ranson et al., 1995, 1997a,b; Kasischke et al., 1995; Dobson et al., 1992, 1995; Le Toan et al., 1992; Kurvonen et al., 1999; Saatchi et al., 2007) and canopy height estimation (Hagberg et al., 1995; Treuhaft et al., 1996, 2004; Askne et al, 1997; Kobayashi et al, 2000; Kellndorfer et al., 2004; Simard, M., et al. 2006, 2008). These applications require ground sampling data for both training and validation purposes.

The signature from these two kinds of sensors bears commonality due to the biophysical and ecological nature of vegetation communities. The vertical distribution of the reflective surfaces revealed by lidar data implies the overall structure supporting the leaf distribution. The relative importance of microwave backscattering from various tree components (e.g. leaves, branches, trunks) depends on the vertical, as well as horizontal distributions of these components. Reflectance from vegetation canopy is controlled by canopy structure as well as the biochemical
composition of the canopy foliage. The use of lidar and radar instruments to measure forest structure attributes such as height and biomass are being considered for future Earth Observation satellite missions. The first such mission to be flown within the next decade is called DESDynI, a combined lidar and radar mission designed to address scientific questions in terrestrial ecosystem structure as well as solid earth and ice dynamics (http://desdyni.jpl.nasa.gov/, Donnellan et al., 2008). In anticipation of this mission, methods for biomass mapping by combining lidar samples and radar imagery need to be investigated.

Data fusion or synergy is required in remote sensing applications, especially for complex tasks such as mapping of forest structural parameters (Patenaude et al. 2005). Synergistic use of various data and approaches has been applied in various studies. For example, Anderson et al. (2008) used waveform lidar with hyperspectral imagery to estimate three common forest measurements - basal area, above-ground biomass and quadratic mean stem diameter in a northern temperate mixed conifer and deciduous forest. Results suggested that the integrated data sets of hyperspectral and waveform lidar provide improved outcomes over use of either data set alone in evaluating common forest metrics. Using Shuttle Radar Topographic Mission (SRTM) and ICESat/GLAS data, Simard et al. (2008) conducted 3D mapping of mangrove forests. Walker et al. (2007) developed the first-ever high-resolution map of canopy heights for the conterminous U. S. using an empirical InSAR-optical fusion approach. In two investigations of radar-lidar synergy, in a North Carolina pine forest (Nelson et al. 2007) and a wildlife habitat analysis (Hyde et al. 2006), authors found that there was little to be gained or only marginal improvement by adding radar data to lidar data. However, the current satellite lidar technology only samples the earth’s surface, whereas radar has the mapping capability required for continuous global biomass mapping. For example Kellndorfer et al, 2010 combined ICESat GLAS, SRTM INSAR and Landsat imagery to make large area estimates of above ground woody biomass and Lefsky (2010) used MODIS and ICESat lidar data together to produce a global map of forest heights. The ecosystem structure component in the DESDynI mission is to measure 3D structure of forests by taking advantage of the spatial continuity of SAR and the direct measurements from lidar samples (Donnellan et al. 2008). This presents a special case for lidar and radar data fusion for mapping forest biomass and other structural parameters globally.

In this study, some issues of combined use of lidar and radar were investigated using data acquired near Howland, Maine, USA. The potential information on biomass from a lidar waveform and the required lidar samples for reliable biomass estimation were studied using field data. The best prediction model was used to generate a reference biomass map from the Laser Vegetation Imaging Sensor (LVIS) data. Random samples were then taken from the biomass map and the correlation between biomass and SAR signature was studied. Proper models were used to extend the biomass...
from lidar samples into all forested areas in the study area. The new biomass map was compared with the reference biomass map derived from LVIS data. The results of the combined use of lidar samples and radar imagery for forest biomass mapping are presented. Biomass mapping was also performed using field data and SAR data to show that the biomass maps from lidar sample and SAR data were better. Various issues in the lidar/radar data fusion for regional biomass mapping are also discussed in this paper.

2. Study site and data

2.1. Site description and field data

The test site for this project is the mixed hardwood and softwood forest of the Northern Experimental Forest (NEF), Howland, Maine (45°15’N, 68°45’W). This site, about 10 Km by 10 Km in size, is used for interdisciplinary forest research and experimental forestry practices. The natural stands in this northern hardwood - boreal transitional forest consist of hemlock-spruce-fir, aspen-birch, and hemlock-hardwood mixtures. Topographically, the region varies from flat to gently rolling, with a maximum elevation change of less than 135 m within the study area. Due to the region's glacial history, soil drainage classes within a small area may vary widely, from excessively drained to poorly drained. Consequently, an elaborate patchwork of forest communities has developed, supporting exceptional diversity in forest structure (Ranson and Sun, 1994). While a significant part of forests were preserved for research purposes, various forest management and harvesting practices have changed the forest structure. Fig. 1 is a false color ASTER image of July 22, 2002 (15m pixel resolution) showing different types of forests in the study area.

A stem map (the larger rectangle in Fig. 1), identifying location, diameter at breast height (dbh) and species for every tree with a dbh greater than 3 cm in a 200 m by 150 m area, was collected in 1989 and again in 2003. This data set will be referred to as stem map data in this paper. This data set served well for model simulation and data analyses in previous studies (Ranson et al., 1997b; Kimes et al., 1997). A metal label was attached to every tree in 1989 to aid identification and re-measurement in 2003. The 2003 dataset includes those trees with dbh greater than 3 cm in 2003 that were not measured in 1989. The canopy biomass can be calculated using dbh from allometric equations listed in Young et al (1980). The corners of the stem map were located using a Trimble differential GPS instrument with an
accuracy of less than 1 meter. Fig. 2 shows locations of trees and the LVIS footprints (circles) within the stem map. A total of 112 footprints were completely inside the stem map.

Twenty sites (Fig. 1 and Table 1) across the study area were sampled in October, 2003 for biomass and other forest parameters. In each site three to four plots with radius of 4 or 7 m were arranged in the center, and 30 m north, south-west, south-east from the center. The dbh for every tree with a dbh > 3cm, and the height, crown length and width of 8 trees in each plot were measured. These sites represent a range of forest structures and biomass levels. The locations of the 2003 sampling sites were determined using a backpack borne Garmin V GPS Unit including a Garmin V Personal Navigator and a MBX-3S Differential Beacon Receiver with known accuracy up to 1 meter, 95% of the time in good receiving conditions. The major parameters of these sampled forest sites were listed in Table 1.

2.2. LVIS data

NASA's Laser Vegetation Imaging Sensor (LVIS) is an airborne laser altimeter system designed, developed and operated by the Laser Remote Sensing Laboratory, Goddard Space Flight Center (GSFC) (Blair et al., 1999). The LVIS system measures the intensity of backscatter returns within 30 cm intervals and the time delay (or traveled distance by laser beam) through the forest canopy. These recorded signals form a vertical profile or lidar waveform of the lidar footprint, which is a direct measurement of the forest structure. In the summer of 2003, LVIS obtained waveform data for forested sites in New England, generating the most detailed forest structural data sets currently available for these regions. The LVIS data used in this study were acquired on July 26, 2003 and processed at GSFC (B. Blair, M. A. Hofton, and D. L. Rabine. 2006; http://lvis.gsfc.nasa.gov). LVIS Ground Elevation (LGE) data were used, which include location (latitude/longitude), surface elevation, and the heights (relative to surface) where 25%, 50%, 75% and 100% of the waveform energy occur. These quartile heights are referred as rh25, rh50, rh75 and rh100 to represent the relative heights in this study. ENVI’s gridding function, which uses Delaunay triangulation of a planar set of points, was used to grid the LVIS LGE data to 15m ASTER base images. Fig. 3-A is a false color image showing the rh50 (R), rh100 (G), and rh25 (B) from LVIS data.

The quartile heights are direct measurements of the vertical profile of canopy components. Waveform measures are a function of the complex and variable 3-D structure of canopy components and their spectral properties, as well as the
spectral properties of the ground/litter. The rh25 and rh50 are lower for the selectively cut areas as seen in Fig. 3-A. In the area around the stem map in Fig. 3-A (the solid red rectangle) all three relative height indices are high so it appears white in the false color image. This corresponds to a forest area without disturbances. When the trees were partially cut (the patch of forest across the road to the east of the stem map), the relative lidar signature returned from tree crowns was reduced and that from the ground surface increased resulting in the lower values of rh25 and rh50, so the false color of the selectively cut area in Fig. 3-A does not appear white but green. Fig. 3-B depicts the centers of LVIS footprints overlaid on the 15m ASTER image, showing that there were more than 20 footprints in a window of 5x5 15m pixels.

2.3. SAR and LANDSAT images

PALSAR images from the Japanese Aerospace Exploration Agency (JAXA) Advanced Land Observing System used in this study are listed in Table 2. Data were ordered as Level 1.1 data. The spatial resolution of the single-look image is 3.556 m and 9.369 m in azimuth and range directions, respectively. As a Level 1.1 product, the data were radiometrically calibrated and in complex format. The data in Table 2 form two pairs of InSAR data, and were processed using ROI_PAC software (Repeat Orbit Interferometry PACkage, http://www.roipac.org/) to create coherence data. SRTM data were downloaded from the USGS site (http://srtm.usgs.gov/), and the height of the scattering phase center was derived from the SRTM DEM minus the surface elevation measured with LVIS. Fig. 4 shows false colour images of SAR data.

While the forest area surrounding the stem map has been preserved for scientific studies, the rest of the forests in the study area have been actively managed. The logging methods were changed from clear-cut in the 1980s, to strip-cuts in the 1990s and to select-cuts (shelter wood cuts) after 2000. Since the data used in this study were from different years of 2000, 2003 and 2007, the logged areas during this period need to be identified. Three LANDSAT ETM+ data acquired
on July, 2, 2000, September 10, 2003 and July 22, 2007 were used to map the changed areas, so they could be omitted for this study.

3. Method

3.1. Image Data Processing

Rasterized LVIS height indices data, SAR data, and the phase center height from SRTM and LVIS DEM data were all co-registered with the 15m ASTER base images. LVIS indices and SAR data were extracted from the co-registered images using windows with various sizes (1x1, 3x3, 5x5) corresponding to various scales (15m, 45m, 75m), respectively.

Definiens Developer 7.0 (Baatz et al., 2004), which allows for the automatic and optimal delineation of local homogenous regions, was used to perform a segmentation of ETM+ images. The polygon segments formed were classified to create a change mask. Fig. 5-A shows the polygon segments overlaid on the 2007 ETM+ images, and Fig. 5-B shows the changed areas identified from the classification of the polygons segments. A mask (Fig. 5-C) was generated to exclude these changed areas and non-forest areas in further analyses. The non-forest areas were identified using rh50 <= 0 since the waveform from an ideal bare surface would have rh50 = 0.

3.2. Biomass estimation from LVIS data

3.2.1. Correlations of forest biomass with lidar waveform indices

The height indices (relative to the ground surface) rh25, rh50, rh75 and rh100 were extracted from LVIS LGE data for each of the LVIS footprints within stem map (Fig. 2). Trees within a diameter of the footprint size of 20m were used to derive the biomass for each footprint, and step-wise regression was performed to select the best prediction model. The correlation was low probably due to the errors in lidar footprint locations and field-measured tree positions.

Aggregation of both biomass measurements and the LVIS indices into a larger unit will reduce measurement uncertainty. The suitable aggregation scale was investigated by randomly sampling the stem map using different pixel sizes. In Fig. 3-B, the square pixels are 15m pixels from ASTER data. A window with 2x2, 3x3, and 5x5 pixels will form pixels with sizes of 30m, 45m and 75m. It can be seen that in most cases, there will be several lidar footprints in one of the 30-75m pixels. The
biomass prediction models at pixel sizes of 15m, 45m and 75m were examined. Thirty points were randomly selected within the stem map, such that a pixel with size of 15m, 45m and 75m was entirely within the stem map. The biomass of these points was calculated from the stem map data using the pixel sizes. The remote sensing data were extracted at these points with a window size of 1, 3 and 5 from co-registered LVIS and SAR data. The stepwise regression function from S-plus (S-Plus, 2010) was used to find the best biomass prediction model. The suitable pixel size for biomass mapping was determined from the analyses.

3.2.2. Prediction model and biomass mapping from LVIS data

The 2003 field samples covered forest sites with very different structures. It was found that when the data were extracted from a 3x3 15m window, the correlations between LVIS height indices and biomass were low. The window size was increased to 5x5 pixels for extracting LVIS and SAR data for the sites sampled in field. The stem map was divided into twelve 50m by 50m sub-plots and the total above-ground biomass of these sub-plots was calculated. The biomass of these sub-plots was (Mg/Ha): 115.3, 119.4, 136.1, 143.8, 149.8, 166.7, 170.9, 175.5, 193.9, 206.5, 209.6, and 210.2. These biomass data were used to develop models to generate biomass from LVIS and SAR data. The stepwise regression was used to pick the best LVIS variables for biomass estimation. An above-ground biomass map from LVIS data was generated using the regression model.

3.3. Forest biomass mapping using field samples and SAR data

The data from SAR include ALOS PALSAR polarimetric data (PLR mode) from two dates (April 16 and June 1, 2007), and dual-pol (HH and HV) images (FSD mode) from two dates (July 10 and August 25, 2007). These PALSAR data were ordered as L1.1, and form two pairs of InSAR data. The data were radiometrically calibrated by JAXA and in complex form (I + jQ). The equation, Normalized Radar Cross Section (NRCS) (dB) = 10*log10((<I^2+Q^2>) + CF - 32.0, where CF= -83.0, provided by JAXA (https://auig.eoc.jaxa.jp/auigs/en/doc/an/20090109en_3.html) was used to convert the complex data to NRCS. The complex coherence (Gaveau et al., 2003) between dual-pol data from July 10 and August 25, 2007 was relatively high, so the coherence was used as a variable for biomass estimation. The ratio of HV to HH was calculated for each of these PALSAR data. For the polarimetric data, the total power (HH+VV+2HV) was also calculated and used as the independent variables. SRTM elevation data represent the elevation of the scattering phase center over the vegetated areas. By subtracting the surface elevation from LVIS data from the SRTM elevation, the height (from the ground surface to the scattering center within the canopy) can be obtained. This height was used as a variable in the regression analyses.
The stepwise regression was used to find the best regression models for biomass estimation when the dependent variable is the field biomass and the independent variables include 1) PALSAR PLR data with and without SRTM phase center height, 2) dual-pol PALSAR data with and without SRTM phase center height, and 3) both PLR and dual-pol PALSAR data with and without SRTM phase center height. The best regression models were used to generate biomass maps from SAR data.

3.4. Extending LVIS biomass samples using SAR data

3.4.1. Mapping biomass using LVIS samples and SAR data

The biomass map from LVIS data was treated as a reference biomass map. The purpose of the study was to investigate the possibility of generating a comparable biomass map using limited samples from LVIS-derived biomass and the SAR imagery. One hundred samples were randomly selected from the areas not masked out by the mask image (Fig. 5-C). The LVIS-derived biomass and SAR signatures at each point were extracted using a 5x5 window. This data set includes the following variables: LVIS derived biomass, srtm-lvis_ht, HH, HV, VV intensity, the total power of two polarimetric SAR images, HH, HV intensities of two dual-pol SAR images, coherence of HH polarization of dual-pol images, and the HV to HH ratio for all SAR images.

The stepwise regression was used to find the best SAR variables for biomass estimation. The regression models were then applied to the same area mapped by LVIS data.

3.4.2. Model performance and error assessments

For each biomass estimation equation, the root mean square error (RMSE) was calculated as $\sqrt{\frac{\sum((B_{\text{pred}} - B_{\text{ref}})^2)}{n}}$. The mean, variance and correlation of the estimated biomass map were calculated and compared. Re-sampling techniques, such as bootstrapping and jackknifing (Efron, 1981) can provide estimates of the standard error, confidence intervals, and distributions for any statistic without the normality distribution assumption. The lidar sampled biomass was randomly picked in the forested area that was not disturbed during the period of 2000-2007. Bootstrapping was used to investigate the stability or reliability of the prediction models.

4. Results

4.1. Biomass mapping from LVIS data

4.1.1. Correlations of forest biomass with lidar waveform indices
When the waveform indices from 112 LVIS footprints within the stem map were used to predict forest biomass for the 20 m footprints, the step-wise regression selected all energy quartiles from LVIS LGE data. The relation between the biomass calculated from the forest stem map data and that predicted by the lidar waveform indices was

\[ B = 17.0 - 10.3 \text{rh25} + 23.0 \text{rh50} - 22.4 \text{rh75} + 13.7 \text{rh100} \]  

(1)

with Multiple R-Squared: 0.315, RSE: 21.1 Mg/ha, F-statistic: 12.17 on 4 and 106 degrees of freedom, and a p-value of 3.543e-008.

To investigate the regression relations at different spatial scale, thirty points were randomly selected within the stem map, such that a pixel with size of 15m, 45m and 75m was entirely within the stem map. The biomass of these points was calculated from the stem map data and the LVIS height indices were extracted at these points with a window size of 1x1, 3x3 and 5x5 from co-registered imagery data. The results from the stepwise regression show that when the pixel size increased from 15 to 45 and 75 meters, the \( R^2 \) increased from 0.171 to 0.496 and then to 0.725. Because of the small size of the stem map, when the pixel size increases, there will be much overlap between sampling points. The range of the biomass also decreases. The increases of \( R^2 \) here may not entirely result from the increase of the pixel size. Nevertheless, the increased averaging reduced the variance of the data caused by the spatial sampling and geo-location mis-matching between lidar footprint and tree locations. The 75m pixel size was used in the following procedures for biomass mapping.

4.1.2. Prediction model and biomass mapping from LVIS data

The best regression equation from stepwise regression using field biomass and LVIS height indices was

\[ B = -1.717 - 6.208 \text{rh50} + 8.625 \text{rh75} \]  

(2)

With a residual standard error (RSE) of 32.91 Mg/ha, Multiple R\(^2\) of 0.70, F-statistic of 34.08 on 2 and 29 degrees of freedom, and a p-value of 2.43e-08. The relationship between field and predicted biomass shown in Fig. 6 was

\[ B_{\text{pred}} = 48.5276 + 0.7015 B_{\text{field}} \]  

(3)

with \( R^2 = 0.70 \), and the RSE of 27.10 Mg/ha. The RMSE calculated from SQRT(SUM((Bpred – Btot)^2)/32) was 31.33 Mg/ha. Fig. 7 is the above-ground biomass map from LVIS data using the equation (2). The model was applied to the entire image, but all the biomass statistics, and the comparisons between different biomass maps were performed on the pixels defined by the mask image (Fig. 5-C).
4.2. Biomass mapping using field biomass data and SAR data

Stepwise regression was used to find the best variables and models for various combinations of the variables from SAR data. Polarimetric and dual-pol data were treated as two groups of data and stepwise regression was applied separately. Table 3 shows the variables selected by stepwise regression, and the RSE, $R^2$, and p-values of these models. It can be seen from these models that the height of scattering phase center (srtm-lvis_ht) is an important variable, but couldn’t predict biomass alone. The coherence of L-band HH data is not a very sensitive variable for biomass estimation. The regression models from 3 and 7 in Table 3 were used to generate the biomass map of the study area. The regression relation between predicted from model 3 and the reference biomass is:

$$B_{pred} = 38.2452 + 0.7019 \ B_{ref}$$  \hspace{1cm} (4)

with $R^2 = 0.7019$, and the RSE of 24.32 Mg/ha. The RMSE is 28.73 Mg/ha. The biomass map from model 3 is shown in Fig. 8. Comparing with Fig. 7, the biomass is obviously high, and spatial distribution pattern is vague.

4.3. Extending LVIS biomass samples using SAR data

The biomass map shown in Fig. 7 was treated as a reference map. One hundred points were randomly picked from the map shown in Fig. 7. The stepwise regression was used to find the best regression models. Table 4 is a list of these models from stepwise regression when different independent variables were used. The stepwise regression selected different variables from those shown in Table 3. Though the $R^2$ in Table 4 are lower than those in Table 3, the RSE and p-value are also lower, because of larger number of data points. Fig. 9 shows the comparison of predicted biomass using SAR data with the reference biomass using the model 7 in Table 4. The regression relation between predicted and reference biomass is:

$$B_{pred} = 38.8803 + 0.7126 \ B_{ref}$$  \hspace{1cm} (5)

with $R^2 = 0.71$, and the RSE of 24.06 Mg/ha. The RMSE is 28.21 Mg/ha. Fig. 10 is the biomass map predicted using this model.
4.4. Model performance and error assessments

Equations 3-5 showed that the regression models for biomass estimation from LVIS-field, SAR-field and SAR-LVIS have similar RMSE and $R^2$. But by applying these models on LVIS or SAR data, the resulting biomass maps are quite different. Table 5 shows the statistics of these biomass maps and the correlations of these maps with the reference maps from LVIS-field data. Fig. 11 shows the histograms of above-ground biomass in the areas not masked out by Fig. 5-C.

First we can see that the two biomass maps from SAR-field are very similar, as are the three biomass maps from LVIS-SAR models. The average biomass from SAR-field models was too high. Stem map is a preserved mature stand with an average above-ground biomass of about 170 Mg/ha. The average biomass of the stem map extracted from the biomass maps using the models listed in Table 5 were 161.6, 200.5, 206.7, 141.3, 159.8 and 173.7 Mg/ha, respectively. Large parts of the forest areas in the study area have been harvested since 1980. The biomass level from Field-LVIS and all LVIS-SAR models is closer to reality (Table 5). The LVIS-SAR models gave similar mean biomass as the Field-LVIS model. The high correlation of these maps with the Field-LVIS map indicates similar spatial distribution patterns as well. The combined RMSE of the two-step models shown in Equations 3 and 5 will be $\sqrt{31.33^2 + 28.21^2} = 42.16$ Mg/ha.

The statistics from bootstrapping of the coefficients of the regression model LVIS-SAR-ALL (Table 5) are shown in Table 6. The means are very close to the observed values and the distributions of these coefficients were close to normal (graphs not shown here).

5. Discussion

5.1. Forest parameters retrieval at lidar footprint scale

The biomass within a lidar footprint was calculated from trees with trunks inside the footprint. The lidar waveform is the result of reflectance from the tree crowns and the ground surface within the lidar beam while the major biomass is from
tree trunks. While a trunk may be inside a footprint, a portion of its crown may fall outside. Similarly, the crown of a nearby tree outside the footprint may be partially illuminated by the lidar beam. This mis-matching will reduce the correlation between the biomass calculated for lidar footprints and the lidar waveform indices. The effect depends on the forest spatial structure and the spatial scales at which the forest parameters are to be estimated. At flat areas, the bigger footprint size will have less edge effect. The direct measurements of lidar waveform are the vertical profile of reflectors within the footprint. It is directly related to the tree or canopy height information, but is not direct measurements of the biomass. The correlation between biomass and lidar waveform indices may depend on the species and spatial structure of forests. To define and determine the biomass in a footprint requires clear understanding of the relations between lidar waveform, crown structure and the biomass of forest stands.

5.2. Aggregation of data into various spatial scales

No matter what models (multivariable regressions, regression trees, neural networks, etc.) are used to retrieve forest physical parameters from lidar waveform indices, several factors will always cause errors, as long as the model is statistical in nature. In addition to the fact mentioned above, the spatial heterogeneity of the canopy determined in part by its successional stage, natural and anthropogenic disturbances, and local terrain will cause more error from uncertainties. These include 1) the uncertainties in field data; 2) the uncertainties in waveform indices, and 3) the mis-matching between locations of field sampling and lidar footprints. Aggregating the data and increasing the samples reduce the uncertainties and improve accuracy. A window of 5 by 5 15m pixels (75m spacing) was used in this study. Because of the discrepancy in data acquisition dates, and inadequate field sampling data, this issue has not been fully explored in this study.

5.3. Forest biomass information in SAR data

This study shows that no single channel of SAR data provides enough information for biomass retrieval, so multiple channels from multiple polarizations, bands and operation modes, and temporal acquisitions were needed. The height of the scattering phase center at C-band from SRTM DEM – LVIS surface elevation was an important variable in this study. Polarimetric SAR interferometry (Pol-InSAR) data has been used to estimate forest height (Cloude and Papanathanassiou, 2003) and then were subsequently converted to forest biomass through forest height-biomass relation (Mette, Papanathanassiou and Hajnsek, 2004; Gaicoya et al., 2010). The DESDynI mission will provide temporal L-band InSAR data. The height of scattering phase center at L band derived from these data if surface DEM is available, and the temporal coherence data may play the similar rule in the biomass estimation. The preference of polarizations of SAR data is not very clear in this
study probably because of the flat terrain of the study area. When terrain slope exists, the effects of terrain on co-
polarization signature will be more significant, so cross-polarization should not be excluded from future missions.

5.4. Comparability of lidar and SAR data for forest biomass estimation

The regression models developed using randomly selected LVIS-derived biomass samples and SAR data can generate
biomass maps comparable to the biomass map from LVIS data at 75m pixel spacing. The multi-channel SAR data can
explain more than 70% ($R^2$ in Table 4) of the variation of the biomass information contained in the LVIS data. It was
found that if the SAR data were used to predict rh50 and rh75, the best regression models selected by stepwise
regression had $R^2$ of 0.7699 and 0.767 (Equations and plots not shown in the paper). The results from this study show
that the SAR data can be used to extend the forest biomass samples at lidar footprints to entire area covered by SAR
data. The mean biomass from Field-LVIS model and LVIS-SAR models are very close. The differences were 4.6%,
4.5% and 7.1% for the three models shown in Table 5. The spatial correlations between the LVIS-SAR biomass maps
and the Field-LVIS map were high: 0.78, 0.78 and 0.8.

5.5. Differences of the biomass maps derived from lidar and SAR data using field data

The biomass map generated from Field-LVIS model is closer to the mean biomass in the study area than the biomass
map generated from Field-SAR model. Theoretically, if both LVIS and SAR data can be used to predict biomass, they
should give similar results. The only reason for this departure is the inadequate samples of the field biomass for
developing the SAR model: it doesn’t cover the proper range of forest structures. In this study the number of samples of
field data is only 1/3 of the random samples, the Field-SAR model can not produce the similar biomass maps generated
from the LVIS biomass samples and the SAR model.

It is also important to note that the PALSAR data were acquired in 2007 and SRTM data was acquired in 2000 while
both the field data and the LVIS data were collected in 2003. Even though the areas with significant changes were
excluded in the analyses, the natural changes, such as tree growth and mortality were not considered in the study. In our
future studies, data collected at the same time and at various scales will be used to further investigate the issue. This
will provide the basis for future analysis.

5.6. Errors in the biomass maps from one step (Lidar only) and two steps (lidar sample and SAR data)

The RMSE of the Field-LVIS prediction model was 31.33 Mg/ha. This can be improved with more field samples, using
more indices from lidar waveform, and more waveform samples by more aggregation. One of the major tasks in
algorithm development for the future DESDynI Mission is improving biomass estimation from the lidar waveform data.
The RMSE of the best LVIS-SAR prediction model (7 in Table 4) was 28.21 Mg/ha. The combined RMSE of the two-step models will be 42.16 Mg/ha. It can be seen from Fig. 9 that the error is relatively even across the entire range (0-250 Mg/ha) of the biomass, which indicates that the “saturation” may not be a huge problem when multiple SAR variables were used. The accuracy of biomass prediction from lidar waveforms should be lower when the biomass is low or trees are shorter, because in these cases the return from vegetation canopy will merge with those from the ground surface. The signature from canopy was hidden in the ground peak, and the index which is most sensitive to biomass (e.g. rh50) is near zero (very close to the ground peak) and is easily affected by the shape of the ground peak. This may need to be addressed when the two-step method is used in the future.

5.7. Comparison of histograms of the biomass maps

Fig. 11 shows that the histogram of Field-LVIS biomass map has two modes. The biomass maps from the LVIS-SAR models have similar means to the Field-LVIS map, but show only little evidence of a bimodal distribution in their histograms. The lower mode of the histogram is around 18-35 Mg/ha, and was from clear cut areas and some other low biomass areas. When the canopy height and biomass are low, the signature from canopy and ground surface will overlap in the lidar waveform, which may cause the uncertainty in biomass estimation from lidar waveform data. This issue may need to be carefully investigated in future studies. The SAR-derived biomass map gave surprisingly high values. This needs to be further investigated, probably by additional field observations.

6. Concluding remarks

The purpose of this study was to prove the concept of combined use of lidar-samples and radar-imagery for biomass mapping. The model relating lidar indices to measured biomass explained 71% of the variation at the aggregated 75m pixel resolution. We used the map of biomass values generated from this model as the reference for this study. The results showed that by selecting 100 samples randomly from the reference map and using these samples to develop a prediction model from SAR data, the model can produce a new biomass map which has similar biomass levels and spatial biomass distributions. There is no obvious biomass “saturation” up to 250 Mg/ha, the limit of our measured field data.

Previously, various studies in SAR biomass estimation have been conducted using field measurements of biomass. The consensus is that both polarimetric and interferometric SAR data can be used to estimate forest biomass up to a certain level, depending on radar wavelength. Multiple channels of SAR data from multi-polarization, temporal, interferometric SAR data and transformations of these data can provide adequate information to extend the biomass information at lidar footprints across entire radar images. How to fully use the information and avoid over fitting will be a future research
The height of the scattering phase center in the C band derived from SRTM data was an important variable in biomass estimation. This work represents a preliminary analysis of possible methods that can be used to combine lidar derived biomass (sampled) with SAR image data to provide detailed maps of accurate biomass. The future DESDYnl mission is expected to rely on data and methods similar to that used here. Of course acquisition of SAR and Lidar data sets at nearly the same time, such as envisioned for DESDYnl should improve the results. New airborne contemporaneous NASA UAVSAR and LVIS data are becoming available along with supporting field measurements. The techniques described herein and other methods can be tested with these data sets.

Acknowledgments

This work is partially supported by NASA Remote Sensing Science Program (grant number NNG06G133G). The LVIS data sets were provided by the Laser Vegetation Imaging Sensor (LVIS) team in the Laser Remote Sensing Branch at NASA Goddard Space Flight Center with support from the University of Maryland, College Park. Funding for the collection and processing of the 2003 Northeastern USA data was provided by NASA's Terrestrial Ecology Program (NASA Grant number NAG512112). Dr. Joanne Howl assisted with final edits of the manuscript.

Table 6. Statistics from Bootstrap of the regression coefficients of model LVIS-SAR-PLR in Table 5. One thousand re-samples were used in the process. The Mean is very close to Observed for all coefficients of the model.
