Submitted to Journal of Geophysical Research – Atmospheres 24 15 November 2011
Abstract

Measurement capabilities of five meteor radars are assessed and compared to determine how well radars having different transmitted power and antenna configurations perform in defining mean winds, tidal amplitudes, and gravity wave (GW) momentum fluxes. The five radars include two new-generation meteor radars on Tierra del Fuego, Argentina (53.8°S) and on King George Island in the Antarctic (62.1°S) and conventional meteor radars at Socorro, New Mexico (34.1°N, 106.9°W), Bear Lake Observatory, Utah (~41.9°N, 111.4°W), and Yellowknife, Canada (62.5°N, 114.3°W). Our assessment employs observed meteor distributions for June of 2009, 2010, or 2011 for each radar and a set of seven test motion fields including various superpositions of mean winds, constant diurnal tides, constant and variable semidiurnal tides, and superposed GWs having various amplitudes, scales, periods, directions of propagation, momentum fluxes, and intermittencies. Radars having higher power and/or antenna patterns yielding higher meteor counts at small zenith angles perform well in defining monthly and daily mean winds, tidal amplitudes, and GW momentum fluxes, though with expected larger uncertainties in the daily estimates. Conventional radars having lower power and a single transmitting antenna are able to describe monthly mean winds and tidal amplitudes reasonably well, especially at altitudes having the highest meteor counts. They also provide qualitative estimates of GW momentum fluxes at the altitudes having the highest meteor counts; however, these estimates are subject to uncertainties of ~20 to 50% and uncertainties rapidly become excessive at higher and lower altitudes. Estimates of all quantities degrade somewhat for more complex motion fields.
Introduction

Gravity waves (GWs) play significant roles in atmospheric dynamics, chemistry, microphysics, and plasma processes extending from Earth’s surface into the thermosphere and ionosphere. At lower altitudes, GWs contribute to boundary layer and mesoscale structures, organize convection, induce turbulence and mixing of relevance to weather prediction and aircraft at flight altitudes. In the middle stratosphere, GWs induce polar stratospheric clouds that contribute to ozone destruction. Throughout the atmosphere, but especially at higher altitudes, GWs systematically influence the large-scale circulation and thermal structure via energy and momentum transport and deposition. These influences are typically slow and systematic at lower altitudes, but may be local and strong accompanying severe events. In the mesosphere and lower thermosphere (MLT), GWs lead to closure of the mesospheric jets, large departures from radiative equilibrium, strong turbulence and mixing of heat, momentum, and constituents, and significant interactions with, and influences on, tides and planetary waves. GWs are expected to have similar, but still largely unknown, effects higher in the thermosphere and ionosphere. Indeed, the vertical transport of horizontal momentum by GWs, and its deposition accompanying GW dissipation, account for the major influences of these motions on the mean and large-scale atmospheric circulation, structure, and variability. Reviews of these various dynamics emphasizing the higher altitudes are provided by Hines [1960], Lighthill [1978], McIntyre [1989], Hocke and Schlegel [1996], Nappo [2002], Fritts and Alexander [2003], Kim et al. [2003], Fritts et al. [2006a], and Fritts and Lund [2011]. The various responses to momentum transport by GWs noted above make this a key quantity in understanding and modeling atmospheric structure at all altitudes. Consequently, significant efforts have addressed these dynamics employing theoretical, modeling, and
73 observational methods, typically focusing on the higher altitudes where the effects of these
74 dynamics are most pronounced [Fritts and Alexander, 2003]. Further quantification of these 75 dynamics
throughout the atmosphere also remain a major research need, given the important of 76 their proper
parameterization for weather and climate forecasting [Kim et al., 2003]. 77 Prior to new meteor radar capabilities,
direct measurements of GW momentum fluxes 78 have only been possible with Doppler radars or lidars having
symmetric, relatively narrow, off79 zenith coplanar beam pairs [Vincent and Reid, 1983; Reid and Vincent 1987;
Fritts and Vincent, 80 1987; Fukao et al., 1988; Reid et al., 1988; Fritts and Yuan, 1989; Fritts et al., 1990, 1992, 81
Hitchman et al., 1992; Nakamura et al., 1993; Murayama et al., 1994; Murphy and 83 Vincent, 1993, 1998; Acott et
al., 2009] or via in situ measurements by aircraft at lower altitudes 84 or chaff measurements in the MLT [e.g., Lilly
and Kennedy, 1973; Lilly et al., 1982; Brown, 85 1983; Meyer et al., 1989; Nastrom and Fritts, 1992; Smith et al.,
2008]. Indirect methods have 86 nevertheless contributed to quantification of, or constraints on, momentum fluxes
employing 87 airglow [e.g., Swenson et al., 1999; Fritts et al., 2002; Espy et al., 2004, 2006], balloon [e.g., 88
Hertzog and Vial, 2001; Hertzog et al., 2008], and satellite measurements [e.g., Ern et al., 2004]. 89 These various
measurements have revealed a variety of responses, including systematic seasonal90 mean momentum fluxes
accounting for large-scale forcing at lower and higher altitudes, 91 responses to specific sources and source regions,
episodic and strong forcing accompanying 92 GWs that are transient and localized, but achieve large amplitudes, and
significant filtering and 93 interactions with larger-scale mean, tidal, and planetary wave (PW) motions. 94 Ideally,
routine momentum flux measurements would provide continuous sensitivity to 95 the magnitudes that are
dynamically important and also capture the temporal variations
accompanying strong, but transient, events that may nevertheless contribute significantly to 97 hourly, daily, monthly, and seasonal means. Improved understanding and parameterization of 98 GW influences also impose a need for such measurements at a range of locations spanning 99 representative source regions for GWs and the environments in which they propagate. Unfortunately, those systems that do (or did) have such measurement capabilities are very limited, their costs are very high (typically ~$1 to 10M, with several much more costly), very few measure continuously, and only two (to our knowledge), sodium resonance lidars at the Arctic Lidar Observatory for Middle Atmosphere Research (ALOMAR) at 69.3°N in Norway and the Andes Lidar Observatory (ALO) at 30°S in Chile, are even at the edges of regions of identified high seasonal GW activity extending into the stratosphere and MLT. So there are considerable motivations for exploring other measurement techniques that may offer the potential to significantly expand such measurements with much cheaper systems. Such systems should also have the potential for continuous measurements; optical systems, whether active (lidar) or passive (airglow, FPI, etc.) cannot provide full diurnal and annual measurements, independent of weather, suggesting that only radar measurements are likely to address this need. The Southern Argentina Agile MEteor Radar (SAAMER) [Fritts et al., 2010a, hereafter F10a] was specifically designed to add a potential for GW momentum flux measurements to the conventional meteor radar capabilities for mean, tidal, and PW measurements for the reasons noted above. This was accomplished by devising a radar beam pattern that yielded a majority of meteors at zenith angles <50° and employing high power to achieve as high a meteor rate as possible at these angles. SAAMER was installed at Rio Grande on Tierra del Fuego, Argentina (53.8°S, 67.7°W) and became operational in May 2008. SAAMER momentum flux measurement capabilities were evaluated using observed meteor distributions for September 2008, a series of
119 test motion fields including prescribed mean winds, diurnal and semidiurnal tide winds, and 120 GWs having various spatial and temporal scales [Fritts et al., 2010b, hereafter F10b], and the 121 analysis procedure suggested by Hocking [2005] employing a “full-field” fit to the various 122 winds, variances, and covariances characterizing the superposed mean winds, tides, and GWs. 123 These suggested that for real wind fields having similar composition and character to the test 124 fields, SAAMER should be expected to provide very good definition of the mean and tidal winds 125 and reasonably good definition of GW momentum fluxes where meteor count rates are sufficient. 126 The apparent success of SAAMER in measuring GW momentum fluxes in addition to 127 mean, tidal, and PW winds was the motivation for a SAAMER clone, the Drake Antarctic Agile 128 MEteor Radar (DrAAMER) that was installed at the Brazilian Antarctic Comandante Ferraz 129 Base (62.1°S, 58.7°W) in March 2010. Comparisons of the mean and tidal winds and the GW 130 momentum fluxes measured by SAAMER and DrAAMER by Fritts et al. [2011, hereafter F11] 131 demonstrated close correspondence between mean and tidal winds at the two sites, as well as 132 significant similarities between the inferred GW momentum fluxes between years and sites from 133 April to June of 2010 and 2011. This agreement suggested significant confidence in the GW 134 momentum flux measurement potential for both radars, given the tests performed with SAAMER 135 data. Nevertheless, we believe it is important to subject DrAAMER to the same tests applied to 136 SAAMER. We also believe that applications of these tests to additional meteor radars having 137 different characteristics (particularly power and beam configuration) may help us identify what 138 radar capabilities are required to achieve GW momentum flux measurements that are sufficiently 139 accurate to be valuable to the community. For example, the Hocking [2005] analysis method was 140 tested with meteor radar data from Socorro, NM and Resolute Bay, Canada and judged to 141 provide reasonable two-month estimates (though without validation). Other meteor radars have
142 also been employed for GW variance, momentum flux, and tidal modulation studies and suggest 143 that more radars may provide enhanced measurement capabilities with testing and suitable 144 analysis techniques [Kumar et al., 2007; Antonita et al., 2008; Clemesha et al., 2009; Mitchell 145 and Beldon, 2009; Placke et al., 2011]. A related study by Vincent et al. [2010] employed a 146 Monte Carlo analysis of measurement capabilities assuming a conventional meteor radar beam 147 pattern and expected radial velocity and angle-of-arrival uncertainties and concluded that 148 accurate momentum flux estimates with such systems would likely require long averages. 149 Our goals in this paper are to evaluate SAAMER and DrAAMER GW momentum flux 150 measurement capabilities relative to several other conventional meteor radars in order to 151 determine 1) what radar parameters are required to enable such measurements, 2) whether other 152 radars can also provide credible GW momentum flux measurements in their current 153 configurations, or 3) whether system upgrades are needed to enable these capabilities. The other 154 radars employed for this assessment are at Socorro (SRO), New Mexico (34.1°N, 106.9°W), Bear 155 Lake Observatory (BL), Utah (~41.9°N, 111.4°W), and Yellowknife (YKF), Canada (62.5°N, 156 114.3°W) (see Hocking, 2005, and Hocking and Kishore Kumar, 2011, respectively, for more 157 detailed descriptions of the SRO and YKF radars). To address these goals, our paper is structured 158 as follows. Section 2 provides a summary of the characteristics of the radars employed for this 159 assessment and the analysis methods used to evaluate the performance of each. Test motion 160 fields, which include mean winds, diurnal and semidiurnal tides, and/or GWs having various 161 characteristics are described in Section 3. The performance of the five radars for the various tests 162 employing real spatial and temporal sampling for each is described in Section 4. Section 5 163 summarizes our findings and discusses measurement accuracies relative to other assessments. 164 Our conclusions are presented in Section 6.
Characteristics of Radars Employed for this Study

We employ five different meteor radars for our assessment of GW momentum flux measurement capabilities in this study. Two of these were specifically designed intending to provide this capability (i.e., SAAMER and DrAAMER); the other three are conventional meteor radars having lower peak power and a single transmitting antenna that had not anticipated such measurements (i.e., the SKiYMET meteor radars previously installed at Socorro, NM, Bear Lake 171 Observatory, UT, and Yellowknife, Canada; see Table 1). The relative locations of the five radars and the meteor distributions for each are shown for one day during the month in Figure 1. Meteor distributions in altitude, by day throughout the month considered, and by hour throughout a composite day for each radar are shown for comparison in Figure 2. The meteor distributions in Figure 1 all exhibit nulls in the polar diagrams that arise from excluding meteors at range increments corresponding to the pulse repetition frequency (PRF) in order to exclude contamination due to ground clutter. SAAMER and DrAAMER use a smaller PRF, and thus have these nulls at larger spacing. The statistics in Figure 2 include meteors at zenith angles from 15° to 60° for all radars. As expected, meteor counts are significantly larger for the radars having higher power, and higher at smaller zenith angles for SAAMER and DrAAMER than for the 181 radars with single-antenna TX systems. They also vary significantly throughout the month, especially at SAAMER and DrAAMER, and exhibit large diurnal variations at all radars. The GW momentum flux measurement potential of SAAMER was previously evaluated for a number of test fields by F10b. Comparisons of SAAMER and DrAAMER measurements for April, May, and June of 2010 and 2011 were presented by F11, and suggested that DrAAMER momentum flux estimates provided a consistent picture of GW momentum fluxes accompanying strong GW sources over the Drake Passage, but did not evaluate the DrAAMER
Momentum flux measurement capability directly. An initial application of the method employed here was also used by Hocking [2005] to estimate two-monthly GW momentum fluxes by 190 SkiYMET meteor radars at Socorro, NM and Resolute Bay, Canada. These estimates were seen to be roughly consistent with expected values, but were not evaluated in detail. However, a systematic evaluation of the relative momentum flux measurement potential of these various radars with specific test fields has not been performed. This is the goal here, and the characteristics of the five radars are described for comparison in Table 1. We employ meteor distributions obtained during June 2011 for KGI and TdF, June 2010 for SRO and BL, and June 196 2009 for YKF, for which meteor counts tend to be larger at northern than at southern latitudes.

3 Specification of Test Motion Fields

We showed in F10b that the SAAMER beam pattern and meteor counts enable relatively high-precision measurements of mean winds and tides over fairly short intervals, and that GW momentum fluxes can be estimated with reasonable accuracies where meteor counts are high, even when the large- and small-scale motion field is variable on multiple time scales. The first measurements over DrAAMER and comparisons with those over SAAMER by F11 suggest that the same can likely be said for DrAAMER. Here we repeat the tests previously applied to 204 SAAMER for DrAAMER and the three conventional meteor radars at Socorro, MN, Bear Lake 205 Observatory, UT, and Yellowknife, Canada in order to evaluate DrAAMER capabilities more completely and determine whether, and under what conditions, useful GW momentum flux measurements may also be possible with the other conventional meteor radars.

Following F10b, we employ real meteor spatial and temporal distributions observed by 209 SAAMER, DrAAMER, and the three other meteor radars during various months to evaluate the measurement capabilities of each. Radial velocities at each meteor location and time for each
radar and each month assessed are specified by each of seven test velocity fields. Each test field includes superposed mean, tidal, and/or GW velocity fields with constant and/or spatially- and temporally-variable tidal and GW amplitudes that are intended to be representative of the scales, amplitudes, and momentum fluxes in the MLT over SAAMER and DrAAMER. Mean, tidal, and GW parameters defining these motion fields for each case are listed in Table 2. The test fields are those employed by F10b, range from highly idealized and stationary to spatially and temporally modulated at large and small scales, and have the following components:

\[
U(x,y,z,t) = U_M + U_d(z,t) \sin(2\pi t/T_D) + U_{sd}(z,t) \sin(2\pi t/T_{SD}) + U_{GW1}(x,y,z,t) \sin(k_1x + l_1y + m_1z - 2\pi t/T_{GW1}) + U_{GW2}(x,y,z,t) \sin(k_2x + l_2y + m_2z - 2\pi t/T_{GW2}) + U_{GW3}(x,y,z,t) \sin(k_3x + m_3z) \]

\[
V(x,y,z,t) = V_M - V_d(z,t) \cos(2\pi t/T_D) - V_{sd}(z,t) \cos(2\pi t/T_{SD}) + V_{GW1}(x,y,z,t) \sin(k_1x + l_1y + m_1z - 2\pi t/T_{GW1}) + V_{GW2}(x,y,z,t) \sin(k_2x + l_2y + m_2z - 2\pi t/T_{GW2}) + V_{GW4}(x,y,z,t) \sin(l_4y + m_4z) \]

\[
W(x,y,z,t) = W_{GW1}(x,y,z,t) \sin(k_1x + m_1z - 2\pi t/T_{GW1}) + W_{GW2}(x,y,z,t) \sin(k_2x + l_2y + m_2z - 2\pi t/T_{GW2}) + W_{GW3}(x,y,z,t) \sin(k_3x + m_3z) + W_{GW4}(x,y,z,t) \sin(l_4y + m_4z) \]
Note that we employ the same test cases defined by F10b, but these Eqs. (1-3) correct several typos appearing in the equations presented in F10b. Each test field includes some or all of the following components: a. zonal and meridional mean winds, Um andVm, b. diurnal and semidiurnal tides having zonal and meridional amplitudes of (Ud, Vd) 235 and (Usd, Vsd) assumed to rotate counterclockwise with time (assuming a southern hemisphere location), and which may have either constant or varying amplitudes with increasing altitude, c. traveling GWs having amplitudes (Ugw, Vgw, Wgw), zonal, meridional, or oblique propagation, spatial and temporal variability, correlated horizontal and vertical motions, and constant or variable momentum fluxes, and d. stationary mountain waves (MWs) having zonal and meridional propagation, only spatial variability, correlated horizontal and vertical motions, and constant momentum fluxes. In each case, the test field amplitudes were chosen to correspond roughly to measured values over SAAMER and DrAAMER on TdF and KGI, which include large semidiurnal tides 246 and GW momentum fluxes [F10a, F10b, F11]. Large semidiurnal tide amplitudes at these sites are consistent with expectations of the most recent version of the Global-Scale Wave Model 248 (GSWM-09) [Zhang et al., 2010a, b, F11]. Large GW momentum fluxes are suggested by the major global hotspot of GW activity in the stratosphere and lower mesosphere centered over the Southern Andes, Drake Passage, and Antarctic Peninsula [F10a, and references therein].

4 Evaluation of Radar Measurement Capabilities
We describe here the performance of each of the five radars for the seven test cases described above. Mean winds, diurnal and semidiurnal tidal amplitudes, and GWs having prescribed spatial and/or temporal variability and momentum fluxes propagating zonally, meridionally, or at other azimuths are defined by Eqs. (1-3) for the seven cases listed in Table 2. Specified and recovered (i.e., the velocity fields inferred from our S-transform tidal fits and the Hocking statistical analysis) profiles of the mean winds, diurnal and semidiurnal tides, and GWs momentum fluxes, and their daily and composite-day hourly variability, where appropriate, are discussed separately for each case below.

b.1. Case 1

Specified fields, and those recovered using observed meteor distributions in space and time for each radar for June 2009, 2010, or 2011 as described above, are shown as monthly means for Case 1 in Figure 3. In this case, tides have only temporal variations and GWs have only horizontal variations, with 50 and 100 km wavelengths in the zonal and meridional motions, respectively (see Table 2). As seen in Figure 3, agreement between specified and recovered fields is highly variable among the five radars. As might be expected based on meteor counts, mean winds and diurnal and semidiurnal tide amplitudes are recovered quite well at KGI, TdF, and BL. Mean winds and diurnal tide amplitudes are recovered within a few percent at each of these sites, with slightly greater uncertainties at BL than at the other two. Semidiurnal tide amplitudes are systematically less than specified at all three sites, but only by ~2-3% at TdF and BL, and by ~5% at KGI. Mean winds and tidal amplitudes exhibit similar tendencies and accuracies at SRO and YKF at the central altitudes, but increasing errors at the lowest and highest altitudes where meteor counts are small.
275 GW momentum flux estimates at KGI, TdF, and SRO are likewise accurate within ~10%, 276 except at KGI and TdF below 79.5 km. In contrast, SRO and YKF exhibit errors of ~20% or 277 larger at intermediate altitudes, again with larger errors where meteor counts are small. 278

b.2. Case 2 279 Case 2 includes no mean winds or tides and only a zonal stationary GW with prescribed 280 horizontal and vertical phase variations with wavelengths of 50 and 15 km (not physical, but 281 simple, see Table 2). Referring to Figure 4, we see that, as in Case 1, the recovered mean and 282 tidal motions are quite accurate at KGI, TdF, and BL, typically within ~2 ms$^{-1}$ or better, except 283 for the tidal amplitudes at BL above ~92 km. Estimates at SRO and YKF are slightly less 284 accurate, within ~5 ms$^{-1}$, but nevertheless quite reasonable, except at the highest and lowest 285 altitudes, especially at YKF. 286 Unlike Case 1, all the radars except YKF provided accurate estimates of GW momentum 287 fluxes in this case, with the largest departures of only ~5 m$^2$s$^{-2}$ at the highest and lowest altitudes 288 shown. However, meteor counts at YKF were apparently too small to yield adequate statistics, 289 except at the central altitudes having the highest meteor counts, from 82.5 to 88.5 km. The 290 significant differences in the accuracies of the GW momentum fluxes at all sites and in the mean 291 wind and tidal amplitudes between Cases 1 and 2 suggest a strong influence of large and variable 292 winds on the quantification of GW momentum fluxes, even for persistent and well-defined GWs. 293 These influences will be quantified further below and discussed in some detail in Section 5. 294

b.3. Case 3 295 Case 3 considers a motion field varying from that of Case 2 only in having two 296 orthogonal GWs, each of which has no phase variation in altitude or time and with the GW 297 propagating in the zonal plane having a large vertical velocity of 10 ms$^{-1}$ (again not physical, but
Results displayed in Figure 5 show that mean motions, tidal amplitudes, and GW momentum fluxes are again described well with the meteor distributions for KGI, TdF, and BL, and the mean motions and GW momentum fluxes are described reasonably at SRO and at YKF, but with increasing errors in momentum fluxes at the higher altitudes. However, tidal amplitudes now exhibit larger errors at SRO and YKF than seen in Case 2, with these motions reasonably defined at ~85 to 92 km at YKF and in the zonal component at SRO, but poorly defined at lower and higher altitudes at both these sites and even at central altitudes in the meridional components at SRO. This cannot be a result of insufficient sampling of the mean and tidal motions, as they are all zero. Instead, the cause appears to be the larger GW vertical velocities that are not sufficiently averaged in defining large-scale (horizontal) winds, despite the validity of the momentum flux estimates for stationary GWs at these sites (see further discussion in Section 5).

We now consider a more complex superposition of mean, tidal, and GW fields given by the sum of the mean and tidal motions in Case 1 and both stationary and propagating GWs in both the zonal and meridional planes (see Table 2). This case differs from the previous cases in that both zonal and meridional GW momentum fluxes now have contributions from stationary and propagating GWs having different spatial structures (with horizontal wavelengths of 30, 40, 50, and 100 km). Case 4 also includes both large semidiurnal tide amplitudes and GW vertical velocities that were suggested above to contribute to errors in the estimates of mean and tidal amplitudes and GW momentum fluxes. Depending on the phases of the four GWs, vertical motions may be ~15 ms$^{-1}$ or larger in this case. Results displayed in Figure 6 show that errors in estimates of the mean winds and tidal amplitudes are comparable (and small) for Cases 1 and 4 at KGI, TdF, and BL. Semidiurnal tide
321 amplitudes are very slightly underestimated, with the largest errors of ~5% at KGI (note the 322 different scales in the third columns of Figures 3 and 6). As seen in Case 1, mean wind and tidal 323 amplitude estimates at SRO and YKF for Case 4 are also reasonable at central altitudes, but 324 exhibit greater errors at lower and/or higher altitudes and at central altitudes in the meridional 325 diurnal tide amplitudes. Turning now to GW momentum flux estimates for Case 4, we see that these are very 327 good at KGI, TdF, and BL, with comparable errors (~a few m$^2$s$^{-2}$) except at the highest and 328 lowest altitudes where they are somewhat larger. Similar estimates are also obtained at SRO and 329 YKF at central altitudes (with errors for Case 4 of ~10 m$^2$s$^{-2}$ or less), with much larger errors 330 occurring at lower and higher altitudes. Apparently, mean winds and large tidal amplitudes do 331 not prevent accurate estimates of GW momentum fluxes when meteor counts are sufficiently 332 high and GWs are sufficiently sustained (whether stationary or propagating) to enable sampling 333 of all phases throughout the month. Large GW amplitudes (especially vertical velocities), 334 however, do cause errors in estimates of means winds and tidal amplitudes where meteor counts 335 are not sufficiently high.  

b.5. Case 5

337 Case 5 explores a superposition of larger mean winds, a larger, but constant, diurnal tide, 338 a semidiurnal tide that exhibits both a 10-day amplitude modulation and amplitude growth with 339 altitude, and four superposed GWs. The latter include 1) stationary GWs having zonal and 340 meridional orientations, constant amplitudes and momentum fluxes, and horizontal wavelengths 341 of 30 and 40 km and 2) propagating GWs having zonal and meridional orientations, horizontal 342 wavelengths of 50 and 100 km, respectively, and amplitude (and momentum flux) modulation 343 by, and anti-correlations with, the semidiurnal tide amplitudes.
Results for Case 5 are displayed in four formats. Figure 7 shows monthly mean profiles of mean winds, tidal amplitudes, and GW momentum fluxes as discussed for Cases 1 to 4 above. Figure 8 displays daily estimates of mean winds and diurnal tide amplitudes throughout the month in the presence of variable semidiurnal tide and GW amplitudes. Figure 9 compares daily estimates of semidiurnal tide amplitudes with the specified variations. Hourly estimates of GW momentum fluxes throughout the composite day are compared with the specified variations in Figure 10. Results shown in Figure 7 reveal mean wind estimates (first column) that are very accurate at all radars (within ~1 m/s except at the lowest and highest altitudes at SRO and YKF). Diurnal tide amplitude estimates (second column) are likewise very good at TdF, nearly as good at KGI and BL (within ~1 to 2 m/s), and reasonable at central altitudes at YKF (within ~2 m/s). Somewhat larger errors (~5 m/s) are again seen in the meridional diurnal amplitude at SRO. Mean semidiurnal tide amplitude estimates (third column) are seen to be very precise at TdF and BL, to exhibit slight underestimates at KGI, and to have comparable errors about the specified mean amplitudes at SRO. Larger errors are seen at YKF (as large as ~5-10 m/s), but the amplitude growth with altitude is still captured at the central altitudes. Daily mean wind and diurnal tide amplitude estimates shown for Case 5 in Figure 8 are most accurate at TdF and BL (with RMS uncertainties of ~1 m/s or less) and somewhat less accurate at KGI (with RMS uncertainties of ~2 m/s), except at the lowest altitude at KGI and the lowest and highest altitudes at BL where meteor counts are small. Daily mean estimates are considerably less accurate at SRO and YKF due to the significantly smaller meteor counts at all altitudes and the asymmetric meteor distributions seen in Figure 1. RMS errors of these estimates range from a few m/s for the zonal components at central altitudes at SRO to ~100% or greater.
uncertainties at YKF that render the latter useless in defining day-to-day variability in these quantities. Estimates of semidiurnal tide zonal and meridional amplitudes for each day in Case 5 at 3-km altitude intervals are displayed in the left and right panels of Figure 9. These estimates are seen to be in close agreement with the specified values (dashed lines) at all but the lowest altitude at TdF and the lowest and highest altitudes for KGI and BL. Estimates at SRO and YKF, in contrast, are reasonably accurate at the central four altitudes, apart from sporadic departures of ~20 to 60 ms$^{-1}$ at these altitudes, primarily at YKF and in the meridional component at SRO. Hourly estimates of zonal and meridional GW momentum fluxes for the Case 5 composite day at 3-km altitude intervals are shown in the left and right panels of Figure 10. These are seen to be close approximations to the specified values at TdF for all but the lowest and highest altitudes, and even to follow the semidiurnal momentum flux modulations at these altitudes, but with larger uncertainties. The results for KGI and BL are comparable and also very good, but exhibit somewhat larger fluctuations about the specified values than seen at TdF at the central four altitudes and increasing uncertainties at KGI at 76.5, 79.5, and 97.5 km and 382 at BL at 76.5, 94.5, and 97.5 km. Composite day hourly momentum flux estimates for SRO and YKF are seen to occasionally follow the specified semidiurnal modulation at 85.5, 88.5, and 91.5 km, but with very large uncertainties. At higher and lower altitudes, these estimates exhibit very large errors.

Case 6

We now compare the ability of the five radars to define mean and tidal motions and GW momentum fluxes for the motion field defined by Case 6 in Table 2. This case includes mean and tidal motions representative of higher latitudes and two transient GW packets having propagation to the east and north and that occur randomly for 3 and 4 hr each day. The two GWs have zonal and meridional propagation, daily mean momentum fluxes of 50 and 25 m$^2$s$^{-2}$, and periods of 20 and 30 min, respectively. Both also have horizontal and vertical phase variations with wavelengths given in Table 2. Inferred monthly mean winds, tidal amplitudes, and GW momentum fluxes obtained with each radar are shown in Figure 11. Hourly estimates of zonal and meridional GW momentum fluxes for a Case 6 composite day at 3-km altitude intervals are shown in the left and right panels of Figure 12. Note here that the composite day momentum flux variations are different for each radar in each component. Case 6 differs from Cases 1 and 4 in having 1) different, but comparable, mean
motions, 2) stochastic rather than uniform (and stationary) GWs, and 3) vertical phase variations of the GWs.

Monthly estimates of mean winds and tidal amplitudes shown in the three left columns of Figure 11 have accuracies and biases that are very similar to those seen previously in Cases 1 and 4. Mean wind and diurnal tide amplitude estimates are again very accurate at TdF and nearly as accurate at KGI and BL. Somewhat greater uncertainties are observed at SRO and YKF, but even these are not larger than ~2 ms$^{-1}$ except at the lowest and highest altitudes. Semidiurnal tide amplitude estimates are also nearly identical to those obtained in Cases 1 and 4. Amplitudes are again under-estimated by ~5% at KGI, SRO, and YKF, and by ~2% at TdF and BL. The similar accuracies achieved in these three cases suggest that the greater intermittency of the larger amplitude GWs in Case 6 does not impact the ability of these radars to provide reasonably accurate definitions of the monthly mean and tidal fields.

GW momentum flux estimates shown in the right column of Figure 11 are seen to be relatively more accurate at KGI, TdF, and BL, where uncertainties are ~10% or less at central altitudes, but approach 20% at KGI and BL at the lowest and/or highest altitudes. Momentum
413 flux estimates are also relatively accurate at SRO and YKF at the central 2 to 4 altitudes having 414 the highest meteor counts, but exhibit large errors at lower and higher altitudes where meteor 415 counts are low. Accuracies at KGI, TdF, and BL are comparable to those seen in Case 1 for 416 which GW amplitudes and momentum fluxes are smaller. However, accuracies are not as good 417 as seen in Case 4 where the zonal momentum flux is largely determined by the stationary, large418 amplitude GW contributing the majority of the momentum flux. 419 Diurnal variability of the composite day zonal and meridional momentum fluxes for each 420 radar shown in Figure 12 reinforce the statements above about the monthly mean profiles. The 421 TdF and BL radars capture the specified momentum flux distributions extremely well, but with 422 slightly greater uncertainties at TdF at the highest altitude, at TdF and BL at the lowest altitude, 423 and a greater loss of sensitivity at the highest altitudes at BL. Momentum flux estimates at KGI 424 are slightly less precise than either TdF or BL at central and lower altitudes, but are somewhat 425 better than at BL at the higher altitudes. In contrast, momentum flux estimates at SRO and YKF 426 are only accurate at the central ~4 and 2 altitudes, respectively, and are susceptible to very large 427 uncertainties below and above. These results suggest that high meteor counts (and more uniform 428 sampling of the motion field) are essential in defining momentum fluxes when GWs are variable 429 and tides achieve large amplitudes. 430 In order to assess whether momentum flux estimates are negatively influenced by large 431 tidal amplitudes, we also performed the same mean, tidal, and GW momentum flux assessments 432 for Case 6, but with zero mean winds and tidal amplitudes. This yielded 1) very accurate mean 433 wind estimates (except at the lower altitudes at YKF), 2) diurnal and semidiurnal tide amplitude 434 estimates of ~1 ms$^{-1}$ at KGI, TdF, and BL and ~2 ms$^{-1}$ at the central altitudes at SRO and YKF, 435 and 3) momentum flux estimates comparable to or slightly more accurate than with the tides
436 present, with the greatest improvements at SRO. Hourly estimates for the composite day without 437 mean winds and tides are likewise of comparable accuracy to those for the full field specified for 438 in Case 6 in Table 2. **Case 7**

*Case 7* 440 Case 7 is very similar to Case 6, with the same mean and tidal winds, but including two 441 intermittent large-amplitude GWs having propagation to the NE and SE. The GW propagating to 442 the NE occurs for 2 hr twice daily at random times; that propagating to the SE occurs for 1 hr 3 443 times daily at random times. The GWs have periods of 20 and 15 min and both horizontal and 444 vertical phase variations. Amplitudes and wavelengths of each are listed in Table 2. Together, 445 they result in mean zonal and meridional momentum fluxes of 75 and -25 m s$^{-2}$, respectively. 446 Inferred monthly mean winds, tidal amplitudes, and GW momentum fluxes obtained with each 447 radar for Case 7 are shown in Figure 13. Figure 14 shows hourly estimates of zonal and 448 meridional GW momentum fluxes for a Case 7 composite day at 3-km altitude intervals. 449 Monthly mean wind, tidal amplitude, and GW momentum flux estimates for Case 7 are very similar to those seen in Case 6 above. Mean wind and diurnal tide amplitude estimates 451 are very accurate at KGI, TdF, and BL but exhibit larger errors at SRO and YKF at the highest 452 and lowest altitudes, respectively. Semidiurnal tides are under-estimated by ~5% at KGI, SRO, 453 and YKF, and by ~2% at TdF and BL, as in Case 6. However, larger errors are seen at SRO and 454 YKF at the highest and lowest altitudes, respectively, as seen for the mean winds and diurnal tide 455 amplitudes. GW momentum flux estimates also exhibit comparable accuracies to those in Case 456 above, suggesting that GW packet duration does not have a strong influence on the ability to define 457 these quantities. Finally, as for Case 6, we also performed these assessments with mean winds 458 and tidal amplitudes specified to be zero. Similar to the results for Case 6, this yielded 1) 459 extremely accurate mean wind estimates (except at the lower altitudes at YKF), 2) diurnal and 460 semidiurnal tide amplitude estimates of ~1-2 ms$^{-1}$ at KGI, TdF, and BL and ~2-5 ms$^{-1}$ at the 461 central altitudes at SRO and YKF, and 3) momentum flux estimates comparable to or slightly 462 more accurate than with the tides present. As in Case 6, hourly estimates for the composite day 463 without mean winds and tides are of comparable accuracy to those for the full field specified for 464 in Case 7 in Table 2. 465

**Summary and Discussion**

We have assessed the relative measurement accuracies of meteor radars having similar 466 frequencies (32.55 to 36.9 MHz) but different antenna configurations, peak power, and sampling 467 modes. Our
evaluation was performed with meteor distributions observed by five radars extending from 62.1° S to 62.5° N obtained during June of 2009, 2010, or 2011 for which meteor statistics tend to be better at northern than southern latitudes. Two of these radars, SAAMER on 471 Tierra del Fuego and DrAAMER on King George Island (53.8 and 62.1° S, respectively) were specifically designed for enhanced measurement capabilities for large-scale motions and GW momentum fluxes. This was accomplished in each case with an 8-Yagi transmitting array directing power into 8 lobes centered at 35° zenith angles separated by 45° in azimuth. The other three radars are conventional meteor radars at northern latitudes (see Figure 1). Our purpose was to determine the relative abilities of different meteor radar configurations to recover specified mean winds, diurnal and semidiurnal tide amplitudes, and GW momentum fluxes. Seven test motion fields included various superpositions of constant mean winds, constant and/or variable tidal amplitudes, and GWs having varying amplitudes, momentum fluxes, scales, periods, propagation directions, and intermittencies. The test fields were sampled according to the observed meteor distributions throughout the month for each radar assuming no radial velocity, range, or angular uncertainties in the measurements. Only meteors at zenith angles between 15 and 60° were used, due to the large altitude uncertainties accompanying ~1° zenith angle uncertainties in angle-of-arrival estimates at larger zenith angles. The various fields were estimated in 3-km altitude bins (centered from 76.5 to 94.5 km) using the method described by F10b, in which mean winds and tidal amplitudes are determined by S-transform fits and removed from each radial velocity distribution before application of the Hocking [2005] method. For each case mean wind, tidal amplitude, and GW momentum flux profiles were determined for monthly and/or daily intervals (as appropriate). Also estimated in cases having diurnal variations in GW momentum fluxes were hourly profiles throughout a composite day. Our evaluation of relative radar performance revealed the following: 1) measurement accuracies depend strongly on meteor counts and antenna beam patterns; accuracies improve with higher meteor counts, smaller zenith angles, and more symmetric beam patterns enabled by crossed antennas, 2) SAAMER (on TdF), having ~12,000 meteors/day between 15 and 60° zenith angles (~120 meteors/hr in a 3-km altitude bin at ~90 km) performed best overall, yielding quite accurate mean wind,
tidal amplitude, and GW momentum flux estimates for all test cases, 498 3) the BL meteor radar and DrAAMER (on KGI) performed comparably and very well, 499 despite DrAAMER having ~30% smaller meteor counts (~8,000 meteors/day compared 500 to ~12,000 total at BL, or ~80 and 120 meteors/hr in a 3-km altitude bin near the peak of the meteor distribution); however, DrAAMER yielded a consistently larger under502 estimate of semidiurnal tide amplitudes (~5% rather than the ~2% seen at BL), and 503 4) the SRO and YKF meteor radars having 6 kW peak power and antenna with only one 504 polarization (having ~ 5,000 and 3,000 meteors/day, respectively, or 50 and 30 505 meteors/hr in 3 km) provided less accurate measurements and over more limited 506 altitudes; they nevertheless described monthly mean winds and tidal amplitudes 507 adequately, with the best results at central altitudes; monthly mean and hourly composite508 day GW momentum flux estimates were generally poor at lower and higher altitudes, but 509 reasonable at ~85 to 90 km. 510 More general conclusions obtained from inter-comparisons of our various cases include 511 the following: 512 5) momentum flux estimates are more accurate when tidal amplitudes are small (or zero) 513 and when GW amplitudes and momentum fluxes are large, 514 6) momentum flux estimates are not significantly impacted by complexity of the GW field, 515 including superposition, multiple scales and frequencies, and intermittency, 516 7) well configured radars (those having symmetric beam patterns (e.g., crossed Yagis) 517 and/or more meteors at smaller zenith angles) capture daily and composite-day hourly 518 variability of total winds and GW MFs well at altitudes where meteor count are high, and 519 8) radars that have asymmetric beam patterns (crossed Yagis) and/or low meteor counts 520 (less than ~25 meteors/hr in 3 km) will likely exhibit significant biases in estimates of 521 daily mean winds and tidal amplitudes; they will likely also exhibit significant biases in 522 estimates of hourly composite-day GW momentum fluxes and variability of these fields 523 on longer time scales. 524 Our assessment of meteor radar performance above assumed no radial velocity, range, or 525 angle-of-arrival measurement uncertainties. Introducing such uncertainties would of course 526 degrade measurement accuracies to some degree in all cases. Here we assess the likely impacts
of such measurement uncertainties for the magnitudes of the mean, tidal, and GW motions and momentum fluxes considered above. If we assume that RMS radial velocity uncertainties are ~1 to 2 \( \text{ms}^{-1} \) (which is a reasonable estimate for SAAMER), then these contributions to measured radial velocities are significantly less than typical radial velocity magnitudes, given the mean winds and tidal and GW amplitudes employed for our assessment. For meteors at the largest zenith angles, ~60°, these uncertainties would contribute little to GW momentum flux assessments given their small implied errors in vertical velocity contributions to radial velocity variance relative to the large contributions by large horizontal velocities. These uncertainties at large zenith angles would also contribute very small errors in estimates of mean and tidal motions, which are obtained by averaging large horizontal motions rather than effectively differencing radial velocity variances for GW momentum flux assessments. At smaller zenith angles, there is a greater potential for influences of radial velocity uncertainties, given that these angles provide greater sensitivity to the differential radial velocities with azimuth that contribute to the momentum flux determination. The most sensitive radars to such uncertainties will be those focusing transmitted power at small zenith angles, specifically SAAMER and DrAAMER, both of which achieve maximum meteor counts at ~35° zenith angles. To assess qualitatively the impacts of radial velocity uncertainties on measurements of GW momentum fluxes, we assume that all meteors occur at the 35° zenith angle of maximum meteor counts for SAAMER and DrAAMER. We then evaluate the relative uncertainty of the momentum flux assessment using the “dual-beam” analysis of Vincent and Reid [1983] for a GW
propagating zonally with superposed tidal winds and nominal radial velocity measurement.

The east and west radial velocities are given by:

\[ V_E = (u' + U_D + U_s) \sin \theta + w' \cos \theta \quad \Delta v_E' \]

and

\[ V_W = -(u' + U_D + U_s) \sin \theta + w' \cos \theta \quad \Delta v_W' \]

where \( u' \) and \( w' \) are the horizontal and vertical GW velocities, \( U_D \) and \( U_s \) are the zonal diurnal and semidiurnal tidal motions (assuming negligible vertical tidal motions and no horizontal 556 phase variations), \( \theta = 35^\circ \), \( \Delta v_E' \) and \( \Delta v_W' \) are the radial velocity uncertainties, and angle brackets denote temporal averaging. Assuming all of the velocities in Eqs. (4) and (5) are uncorrelated except for \( u' \) and \( w' \), which are in phase or antiphase, squaring, subtracting Eq. (5) from Eq. (4), and rearranging, the measured momentum flux may be written as:

\[ <u'w'>_M = \frac{(V_E^2 - V_W^2 + \Delta v_E'^2 - \Delta v_W'^2)}{2 \sin(2 \theta)} \]

where \( <u'w'>_T \) is the true GW zonal momentum flux for the specified motion field. The fractional uncertainty in the measured momentum flux is then:

\[ \frac{\Delta <u'w'>}{<u'w'>_T} = \frac{\Delta v_E'^2 - \Delta v_W'^2}{<u'w'>_T 2 \sin(2 \theta)} \]

Thus, fractional uncertainties are minimized if radial velocity uncertainty variances are small relative to the true GW momentum flux, as \( 2 \sin(2 \theta) = 1.88 \) for the zenith angle specified. The largest magnitude of the numerator occurs if the radial velocity uncertainty variance is negligible in one beam. But for the uncertainties assumed above, this is \( \Delta v'^2 \sim 3 \text{ m}^2 \text{s}^{-2} \), with likely values 569 significantly smaller. By comparison, mean GW momentum fluxes in the MLT are typically \( \sim 10 \text{ m}^2 \text{s}^{-2} \), with peak values \( \sim 3 \) to 10 times larger, at most locations, with values over the Drake Passage “hotspot” expected (and measured, see F10b) to be \( \sim 2 \) to 5 times larger. These values
suggest a maximum fractional uncertainty of the momentum flux due to radial velocity uncertainties of \( \sim 15\% \) at typical sites and \( \sim 5\% \) in GW source hotspots. We anticipate range uncertainties comparable to the range resolution of 2 km and angle-of-arrival uncertainties of \( \sim 1^\circ \) in zenith angle and \( \sim 1.5^\circ \) in azimuth. These imply that altitude uncertainties are defined by zenith angle uncertainties near zenith angles of \( \sim 60^\circ \) and by range uncertainties at smaller zenith angles. At all zenith angles, however, these values suggest altitude uncertainties comparable to or smaller than our chosen 3-km altitude bin. Thus range and angle-of-arrival uncertainties appear unlikely to significantly impact measurements of mean and tidal winds having large vertical scales or GW momentum fluxes that rely most on radial velocities occurring at smaller zenith angles. These results suggest that measurement uncertainties are likely to contribute much less to momentum flux uncertainties than inadequate definition of the mean, tidal, and GW fields due to low meteor counts arising due to low radar sensitivity or small averaging intervals and/or range bins. Several previous studies have assessed the potential for momentum flux measurement uncertainties due to inadequate sampling of the motion field. Kudeki and Franke [1998] and Thorsen et al. [2000] evaluated momentum flux measurements employing the “dual-beam” technique and concluded that very long averaging intervals were required to achieve statistical significance. Kudeki and Franke [1998] assumed the GW velocity fields to be defined by Gaussian distributions with a net momentum flux equal to 1% of that assuming a single GW was present and inferred a required integration time of 16 days. This assumption, however, is in contradiction to the strong correlations among component velocities that often occur when one or several large-amplitude GWs dominate the high-frequency motion field and the total momentum flux, as is often observed. In such cases, the averaging time implied by the Kudeki and Franke
595 [1998] would decrease by 2 decades or more. Examples of dual-beam or multiple-beam
596 measurements employing MF, VHF, and UHF radars that provide clear evidence for significant 597 and variable
GW momentum fluxes (magnitudes as large as \( \sim 70 \, \text{m} \, \text{s}^{-2} \)) occurring on time scales 598 as short as a few hours or less
include the following: 599 1) MLT measurements with the MF radar at Buckland Park, Australia showing clear
diurnal 600 tide modulation of GW momentum fluxes with a modulation amplitude of \( \sim 30 \, \text{m} \, \text{s}^{-2} \) [Fritts and
Vincent, 1987], 602 2) MLT measurements with the SOUSY VHF radar at Andoya, Norway revealing 603
momentum fluxes (per unit density) of \( \sim 66 \, \text{m} \, \text{s}^{-2} \) over \( \sim 3 \) hours [Reid et al., 1988], 604 3) troposphere and
stratosphere measurements using the MU VHF radar at Shigaraki, Japan 605 for multi-beam measurements of GW
momentum fluxes over 6 days that exhibit clear 606 episodic enhancements as short as an hour simultaneously in
multiple beams and 607 spanning multiple altitudes [Fritts et al., 1990], 608 4) MLT measurements employing the
former VHF radar at Poker Flat, Alaska that revealed 609 clear anti-correlations between diurnal and semidiurnal
tide winds and GW momentum 610 fluxes over 4 and 16 day intervals exhibiting stronger momentum flux
modulations (\( \sim 5 \) to \( 10 \, \text{m} \, \text{s}^{-2} \)) accompanying larger tidal amplitudes [Wang and Fritts, 1991], 612 5) MLT
measurements spanning two 10-day intervals with the Jicamarca VHF radar in Peru 613 that exhibit daily mean
momentum fluxes of \( \sim 10 \, \text{m} \, \text{s}^{-2} \) and maxima of \( \sim 30 \, \text{m} \, \text{s}^{-2} \), with 614 hourly profiles exhibiting significant coherence in
altitude and time and maximum 615 magnitudes of \( \sim 60 \, \text{m} \, \text{s}^{-2} \) [Fritts et al., 1992],
616 6) MLT measurements with the MF radar at Buckland Park, Australia exhibiting clear diurnal modulation of GW momentum fluxes by a large-amplitude 2-day wave [Murphy and Vincent, 1998], 619 7) MLT measurements employing the dual-beam Arecibo UHF radar that revealed variable GW momentum fluxes often near zero, but exhibiting occasional maxima as large as \( \sim 50 \) \( \text{m}^2\text{s}^{-2} \), that were largely anti-correlated with the large-scale wind field [Fritts et al., 2006b], and 623 8) MLT measurements spanning \( \sim 8 \) hr employing the Arecibo UHF radar that revealed very significant GW activity, but with momentum fluxes that were very small, suggesting ducting [Fritts and Janches, 2008]. 626 A more recent study by Vincent et al. [2010] employed numerical simulations of test GW fields with a statistical model of radial velocity and angle-of-arrival uncertainties to evaluate the accuracy of meteor radar measurements of mean winds and GW velocity variances and momentum fluxes as functions of the meteor rate within a 2-km range bin. These authors concluded that mean winds could be determined with relatively few meteors, but that estimation of GW variances, and especially momentum fluxes, with small uncertainties required considerable averaging enabling large meteor counts. The meteor counts employed to assess measurement capabilities in the study ranged from 10 to 200. 634 By comparison, our assessment above assumed a need for significant meteor counts, with the typical averaging interval for definition of mean and tidal winds and GW momentum fluxes being a month, but with mean wind and semidiurnal tide assessments also evaluated for one day or for one hour of a composite day for the month (hence 24 or 30 hr of data). Employing real meteor distributions observed during a test month for each of five radars (June of 2009, 2010, or
these yielded meteor counts in a 3-km altitude bin at the peak of the meteor distribution for the month of ~80,000 at TdF, ~70,000 at BL, ~40,000 at KGI, and ~25,000 at SRO and YKF. Meteor counts at the upper and lower edges of these distributions varied by radar, but were typically smaller by ~2 to 4 times. Daily and composite-day hourly assessments employed ~3 and 4% of these meteor counts, respectively. Thus, in all cases, our meteor counts for each radar were significantly larger than those assessed by Vincent et al. [2010] near the peak of the meteor distribution. Assuming that accuracies vary as the signal-to-noise ratio (S/N) and thus as \(N^{1/2}\), where \(N\) is the meteor count, we can compare our inferred accuracies with those of Vincent et al. [2010]. As noted above, the radars at BL, TdF, and KGI have peak monthly meteor counts of \(N \approx 40,000\) to 80,000 in a 3-km altitude bin, with \(N \approx 10,000\) to 25,000 at the edges of the distributions. These imply reductions by factors of ~15 to 25 in the mean wind measurement errors at the meteor distribution peak relative to the 5 ms\(^{-1}\) uncertainties displayed by Vincent et al. [2010] in Table 1, with reductions by factors of ~10 at the highest and lowest altitudes. Inspection of the monthly mean winds for the seven cases considered above suggests that our results are largely consistent with that expectation. Similarly, we expect error reductions of ~4 and 2 in the center and edge regions for daily mean winds, implying errors of ~1 to 3 ms\(^{-1}\). These are largely consistent with the daily mean winds inferred for our Case 5 test fields displayed in Figure 8. Finally, meteor counts at SRO and YKF suggest monthly mean wind uncertainties smaller than ~5 ms\(^{-1}\) uncertainties of Vincent et al. [2010] by ~12 and 5 in the center and edge regions. In these cases, our uncertainties seem to be comparable to, or somewhat larger than, those expected. We note, however, that the antenna patterns implied by the meteor locations shown in Figure 1 suggest significant asymmetries that likely also contribute to measurement errors.
Applying the same factors to our momentum flux estimates, we expect to see errors of
663 ~10 and 25% for the monthly means at the center and the edges of these distributions. Again, our 664 results are consistent with these expectations, though with variations that depend on the 665 complexity of our motions fields and the meteor distribution of each radar. Note, in particular, 666 that Vincent et al. [2010] did not include tidal winds in their assessment, but that variable tidal 667 winds can induce apparent mean winds and GW momentum fluxes if the meteor distribution is 668 not approximately uniform in space and time. Our results also are relatively more accurate for 669 cases having constant GW character throughout the month; they are less accurate for Cases 6 and 670 7 for which GWs are randomly distributed and likely more similar to the GW spectra specified 671 by Vincent et al. [2010]. We cannot assess the contributions of the assumed radial velocity and 672 angle-of-arrival uncertainties employed by Vincent et al. [2010] to the overall uncertainties 673 displayed in their Table 1. However, our own assessment of radial velocity uncertainties above 674 suggests that the majority of the measurement errors seen in our results can be attributed 675 primarily to the expected dependence on meteor counts.

**Conclusions**

Our assessment of meteor radar measurement capabilities presented in previous sections has demonstrated both 1) clear capabilities for quantitative measurements of mean winds, tides, and GW momentum fluxes by radars that achieve sufficiently high meteor counts and provide sensitivity to radial velocities at sufficiently small zenith angles, and 2) strong dependence of these measurement capabilities on radar power, beam geometry and sensitivity, and spatial and temporal meteor distributions.
Meteor radars that combine high power, high meteor counts at small zenith angles, and symmetric beam patterns exhibit the smallest measurement errors. Those having low power, acquiring a majority of meteor detections at large zenith angles, and/or experiencing beam or meteor detection asymmetries exhibit much larger measurement uncertainties, thus either requiring longer averaging intervals or precluding the more challenging measurements, especially estimations of GW momentum fluxes. Monthly mean winds can typically be measured to within 1 ms$^{-1}$ over ~15 to 20 km, with maximum accuracies between ~85 and 90 km, for radar frequencies near 35 MHz and having higher power that conventional meteor radars. These radars can also provide daily mean winds having accuracies of ~1 to 3 ms$^{-1}$ where meteor counts are sufficient, even in the presence of large tidal motions. Monthly mean diurnal and semidiurnal tide amplitudes are also recovered very well by higher-power meteor radars, but typically with amplitude under-estimates of a few %. Mean winds and tidal amplitudes are recovered much more accurately, however, by meteor radars that achieve high meteor counts at small zenith angles compared to meteor radars achieving the same meteor counts, but at larger zenith angles. GW momentum flux estimates are challenging for meteor radars because of the large number of meteors required to adequately resolve differences in radial velocity variances at opposite azimuths. Nevertheless, accurate estimates over sufficiently long time scales (typically averages over ~1 to 30 days) appear to be possible with sufficient meteor counts (~2,000 to 60,000 in an altitude bin). Accuracies are also enhanced with high meteor counts at small zenith angles, given the greater sensitivity of these radial velocities to the correlations between horizontal and vertical velocities within the GW field. Importantly, meteor radars appear to measure momentum fluxes for stationary and propagating GWs, for complex GW superpositions, and for GW fields exhibiting significant intermittency equally well on monthly time scales.

</table>
fluxes for each case are shown at the bottom. Units for velocities, wavenumbers, and periods are 886 $\text{ms}^{-1}$, $\text{km}^{-1}$, and min, and $T_M = 10 \text{ days}$ and $T_{SD} = 12 \text{ hrs}$. GWs in Case 6 are modulated by 887 amplitude functions $F_6(t) = 1 (t$
and $F_6(t) = 0$ otherwise, and $G_6(t) = 1$ ($0 \leq 4.888 \text{ h} + 20R_2 \text{ hr}$) and $G_6(t) = 0$ otherwise, with $R_1$ and $R_2$ random variables chosen between 0 and 1. For each of the 30 days of the test...
GWs in Case 7 are modulated by amplitude functions

\[ F_7(t) = 1 \quad (t = 0-2 \text{ and } 8-10 \text{ h } + 14 \text{R}_3 \text{ hr}) \]

and \( F_7(t) = 0 \) otherwise,

and \( G_7(t) = 1 \quad (t = 0-1 \text{ h } 891 \text{ and } 6-7 \text{ h } \text{ and } 10-11 \text{ h } \text{ and } 19-20 \text{ h } + 4 \text{R}_3 \text{ hr}) \)

and \( G_7(t) = 0 \) otherwise,
otherwise, with \( R_3 \) and \( R_4 \) random variables between 0 and 1 as above.

Figure Captions

Figure 1.

Daily meteor distributions illustrating
g the beam patterns for the five radars employed in this assessment of measurement capabilities. The radar locations and frequencies are listed in each panel. The radars at BL, TdF, and KGI use
crossed Yagi antennas and have nearly 910 symmetric beam patterns; The radars at YKF and SRO, however, use uncrossed (linearly-polarized) Yagis oriented north-south and east-west, respectively, resulting in...
in the asymmetric meteor distributions favoring east-west and north-south measurements, respectively, at those 913 sites. Nulls at various radii in the meteor detections are due to removal of meteor
detections that 914 may have ground clutter contamination. 915

Figure 2. Accepted meteors employed for mean and tidal wind and momentum flux estimates 916 for each radar (labeled at left). Meteor distributions are shown as
monthly counts in each 500 m range bin,
counts per day, and counts per hour for a composite day.
These statistics include meteors at zenith angles between 15 and 60° for all radars examined.
Figure 3.

Monthly mean winds, (second column) diurnal tide amplitude s, (third column) semidiurnal tide amplitude s, and (right) GW momentum fluxes for Case 1. Solid
dashed 921 lines denote zonal and meridional profiles and the radars are designated at the left of each row. 922 Vertical dashed lines show specified values.

Figure 4.
As in Figure 3, but for Case 2.

Figure 5.
As in Figure 3, but for Case 3.

**Figure 6.**
As in Figure 3, but for Case 4.

**Figure 7.**
As in Figure 3, but for Case 5.
Figure 8. Daily (left) zonal mean winds, (second column) meridional mean winds, (third column) zonal diurnal tide amplitudes, and (right) meridional diurnal tide amplitudes for Case 5. Vertical dashed lines show specified values. Figure 9. Daily (left) zonal and (right) meridional semidiurnal tide amplitudes for Case 5 for the five radars (labeled at the top of the left panels). Colored lines show measured amplitudes from (black) 76.5 to (red) 97.5 km, dashed lines show specified amplitudes. Figure 10. Hourly (left) zonal and (right) meridional GW momentum fluxes for Case 5 for a composite day for the five radars (labeled as in Figure 9). Colored lines show measured amplitudes from (black) 76.5 to (red) 97.5 km. Dashed lines show specified amplitudes. Figure 11. As in Figure 3 for Case 6. Figure 12. As in Figure 10, but for Case 6. Figure 13. As in Figure 3 for Case 7. Figure 14. As in Figure 10, but for Case 7.
