Aerosols are small particles suspended in the atmosphere and have a variety of natural and man-made sources. Knowledge of aerosol optical depth (AOD), which is a measure of the amount of aerosol in the atmosphere, and its change over time, is important for multiple reasons. These include climate change, air quality (pollution) monitoring, monitoring hazards such as dust storms and volcanic ash, monitoring smoke from biomass burning, determining potential energy yields from solar plants, determining visibility at sea, estimating fertilisation of oceans and rainforests by transported mineral dust, understanding changes in weather brought upon by the interaction of aerosols and clouds, and more.

This paper evaluates a new dataset which provides AOD over land from Sea-viewing Wide Field-Of-View Sensor (SeaWiFS) measurements. The dataset is available free of charge from http://disc.gsfc.nasa.gov/dust. The advantage of SeaWiFS is that up to now it provided a longer time series (late 1997 to December 2010) of measurements than any other sensor used for determining column AOD. The quality of the data is comparable to that from other satellite sensors.

Abstract:

This study evaluates a new spectral aerosol optical depth (AOD) dataset derived from Sea-viewing Wide Field-of-view Sensor (SeaWiFS) measurements over land. First, the data are validated against Aerosol Robotic Network (AERONET) direct-sun AOD measurements, and found to compare well on a global basis. If only data with the highest quality flag are used, the correlation is 0.86 ± 5 and 72% of matchups fall within an expected absolute uncertainty of 0.05 ± 20% (for the wavelength of 550 nm). The quality is similar at other wavelengths and stable over the 13-year (1997-2010) mission length. Performance tends to be better over vegetated, low-lying terrain with typical AOD of 0.3 or less, such as found over much of North America and Eurasia. Performance tends to be poorer for low-AOD conditions near backscattering geometries, where SeaWiFS overestimates AOD, or optically-thick cases of absorbing aerosol, where SeaWiFS tends to underestimate AOD. Second, the SeaWiFS data are compared with midvisible AOD derived from the Moderate Resolution Imaging Spectrometer (MODIS) and Multiangle Imaging Spectroradiometer (MISR). All instruments show similar spatial and seasonal distributions of AOD, although there are regional and seasonal offsets between them. At locations where AERONET data are available, these offsets are largely consistent with the known validation characteristics of each dataset. With the results of this study in mind, the SeaWiFS over-land
Multiannual average annual cycle of AOD from a variety of different satellite datasets, for different regions of the world. This illustrates the differences in AOD in different regions (due to different aerosol sources and transport pathways), as well as the general consistency between the satellites' estimates of seasonality. It also, however, highlights remaining uncertainties related to small offsets between the datasets; understanding these will help to improve future versions of the data.
Global and regional evaluation of over-land spectral aerosol optical depth retrievals from SeaWiFS

Abstract. This study evaluates a new spectral aerosol optical depth (AOD) dataset derived from Sea-viewing Wide Field-of-view Sensor (SeaWiFS) measurements over land. First, the data are validated against Aerosol Robotic Network (AERONET) direct-sun AOD measurements, and found to compare well on a global basis. If only data with the highest quality flag are used, the correlation is 0.86 and 72% of matchups fall within an expected absolute uncertainty of 0.05 + 20% (for the wavelength of 550 nm). The quality is similar at other wavelengths and stable over the 13-year (1997-2010) mission length. Performance tends to be better over vegetated, low-lying terrain with typical AOD of 0.3 or less, such as found over much of North America and Eurasia. Performance tends to be poorer for low-AOD conditions near backscattering geometries, where SeaWiFS overestimates AOD, or optically-thick cases of absorbing aerosol, where SeaWiFS tends to underestimate AOD. Second, the SeaWiFS data are compared with midvisible AOD derived from the Moderate Resolution Imaging Spectrometer (MODIS) and Multiangle Imaging Spectroradiometer (MISR). All instruments show similar spatial and seasonal distributions of AOD, although there are regional and seasonal offsets between them. At locations where AERONET data are available, these offsets are largely consistent with the known validation characteristics of each dataset. With the results of this study in mind, the SeaWiFS over-land AOD record should be suitable for quantitative scientific use.
1 Introduction

The remote sensing of aerosol optical depth (AOD) from satellites over land is generally more complicated than over ocean. Reasons for this include a brighter and more heterogeneous surface reflectance, diversity in aerosol microphysical properties, difficulties in cloud identification, and, particularly near strong aerosol sources, heterogeneity of the aerosol itself. The limited information content of current and previous passive satellite imaging radiometer measurements (Hasekamp and Landgraf, 2007) has led to the development of many different AOD retrieval algorithms, utilising the strengths and mitigating the weaknesses of each sensor (e.g. Kokhanovsky and de Leeuw, 2009).

Retrieved AOD from these datasets is typically evaluated using ground-based estimates of AOD, from measurements of the extinction of direct solar radiation using sun-photometers (e.g. Ichoku et al., 2002, Kahn et al., 2010, Levy et al., 2010, Sayer et al., 2012). The methodology adopted in this work draws from these studies. This evaluation is an important component in establishing the reliability of the satellite data for scientific use, such as in studies of air quality (Gupta and Christopher, 2008, Hoff and Christopher, 2009), radiative forcing (Chylek et al., 2003, Bellouin et al., 2005), or trend detection (Zhang and Reid, 2010, Yoon et al., 2011). The difficulty of accurate AOD retrieval over land has so far limited some of these applications (e.g. Li et al., 2009).

At the time of writing, the longest single-sensor record suitable for determination of column AOD over land and ocean surfaces is the Sea-viewing Wide Field-of-view Sensor (SeaWiFS), which was in operation between September 1997 and December 2010, with a small number of temporary outages. The main focus of the SeaWiFS mission was determination of ocean color parameters (McClain et al., 2004). Due to the small contribution of the ocean to the reflected solar radiance at top-of-atmosphere (TOA), this requires a highly accurate and stable calibration, which was maintained over the mission (Eplee Jr. et al., 2011; of order 1-3 % absolute calibration accuracy, and temporal stability around 0.3 %). The long time series and quality of calibration make SeaWiFS a good candidate sensor for the creation of an AOD dataset. With an equatorial crossing time around noon (albeit drifting into the early afternoon in its final few years), SeaWiFS’s sampling time was in between other satellite platforms which carry instruments suitable for AOD retrieval (e.g. Terra, ERS-2, or Envisat in the mid-morning, and the A-Train in the early afternoon).

For these reasons, the Deep Blue Utilization of SeaWiFS Through the Data and Information Services Center (DUST-DISC) project has created such an AOD record from SeaWiFS. The current version (v003) is freely available from http://disc.gsfc.nasa.gov/dust/ along with supporting documentation for users. Both Level 2 (individual orbit) and Level 3 (daily/monthly gridded composite) products are available. Further information about the dataset, including details and validation of the algorithm used over water, is provided by Sayer et al. (2012). The over-land AOD retrieval draws on the heritage of the ‘Deep Blue’ algorithm (Hsu et al., 2004, 2006), which is part of the operational MODerate Resolution Imaging Spectroradiometer (MODIS) processing, and will be described in a forthcoming publication. The aim of this paper is to evaluate the over-land AOD dataset through
validation of Level 2 AOD retrievals with Aerosol Robotic Network (AERONET) data (Holben et al., 1998) and comparison with other satellite AOD datasets derived from MODIS and Multiangle Imaging Spectroradiometer (MISR) measurements on a Level 3 basis.

Section 2 describes the satellite and ground-based data used in the study, and Section 3 presents some general results concerning the dependence of comparison statistics on factors such as geometry and data quality flags. Next, Section 4 discusses individual regions in more detail. Finally, Section 5 summarises the main results of the study.

2 Datasets and methodology used

The over-land SeaWiFS aerosol dataset provides retrieved AOD at the commonly-used reference wavelength of 550 nm, at the SeaWiFS bands centred near 490 nm and 670 nm, and, over some surface types, the band centred near 412 nm. The primary quantity of interest is the AOD at 550 nm, \( \tau_{550} \), where the subscripted number indicates the wavelength in nm. Unless otherwise specified, references to AOD imply \( \tau_{550} \). Each Level 2 retrieval pixel has an associated quality assurance (QA) flag with a value between 1 and 3, with 3 indicating the most confidence in the retrieval and 1 the least; over land, only QA=3 retrievals are used to create the Level 3 products. The comparisons presented in this paper can be divided into two types, described in the succeeding sections.

2.1 AERONET validation

Comparison of spectral AOD with AERONET data on a Level 2 basis helps to establish the reliability of the SeaWiFS data in many different aerosol/surface regimes. The AERONET record provides spectral AOD in several bands between the ultraviolet (UV; 340 nm) and shortwave infrared (swIR; 1,640 nm) with an uncertainty of order 0.01-0.02; the larger uncertainties are found in the UV (Holben et al., 1998, Eck et al., 1999). The exact band configuration depends on the specific instrument. The validation protocol is as adopted in Sayer et al. (2012), and previously-cited studies. AERONET provides a point measurement with a temporal resolution around 15 minutes, while SeaWiFS provides a single-time measurement with a spatial footprint of 13.5 km×13.5 km (at the sub-satellite point). Additionally, AERONET samples the direct atmospheric path between the Sun and the site, while SeaWiFS measures light which has traveled this path and then been reflected into the viewing direction. To mitigate these sampling differences, the former dataset is averaged in time, and the latter in space. A valid matchup is defined when there is at least one AERONET measurement within 30 minutes of the satellite overpass, and at least one SeaWiFS retrieval in a 25 km radius of the AERONET site.

Only cloud-screened and quality-assured Level 2.0 AERONET data (Smirnov et al., 2000) are used. A total of 183 AERONET sites, which each provide at least 10 matchups when the SeaWiFS data are restricted to the highest quality flag (QA=3), are used. Note that only 109 of these sites
include a comparison of AOD at 412 nm (due to absence of AERONET and/or SeaWiFS data in the relevant bands).

As the SeaWiFS and AERONET bands do not match, in this study the AERONET AODs are interpolated spectrally to the relevant SeaWiFS wavelength using the Ångström power law, $\alpha = d\ln \tau / d\ln \lambda$, where the Ångström exponent $\alpha$ used for this interpolation is provided in the standard AERONET data product, and the interpolation uses the spectrally-closest $\tau$ and $\alpha$ to the desired SeaWiFS wavelength. The spectral variability of AOD is generally smooth, so the error introduced by this interpolation is negligible. AERONET data are denoted with a subscripted A, i.e. $\tau_A$. The SeaWiFS dataset provides $\alpha$ evaluated between 490 nm and 670 nm; this is also compared with the closest AERONET $\alpha$ (440 nm-675 nm), and unless specified otherwise, further references to $\alpha$ indicate this combination.

2.2 Multi-satellite comparison

The second type of comparison involves satellite-derived midvisible AOD (550 nm for SeaWiFS and MODIS, 558 nm for MISR). In the interests of brevity, and because 550 nm is a common reference, only this one quantity is considered. As sampling and aggregation choices can have significant effects on such comparisons (Levy et al., 2009, Sayer et al., 2010), to minimise the effects of spatio-temporal mismatch between the data, daily Level 3 data are used. The purpose of this is to show how the SeaWiFS data compare to the widely-used MODIS and MISR products on a global and regional scale. Multiple publications have already addressed the comparison of over-land MODIS and MISR data products with AERONET and each other (Liu and Mishchenko, 2008, Kahn et al., 2009, Mishchenko et al., 2009, Kahn et al., 2010, Levy et al., 2010, Mishchenko et al., 2010, Hyer et al., 2011, Kahn et al., 2011, Shi et al., 2011), so this will only be discussed where relevant in the context of SeaWiFS. The local overpass times of the satellites vary between late morning and early afternoon; Smirnov et al. (2002) observed that variability of AOD between these times is of order 10% of the daily mean AOD or less for most aerosol types, and so is unlikely to be a major contributing factor to observed offsets in many regions (although aerosol transport may contribute to scatter).

The comparison uses the standard Level 3 daily products for the period 2006-2010. For MISR, this is the version 22 dataset (Martonchik et al., 2009, Kahn et al., 2010). For MODIS, two sets of products are considered. Firstly, the MODIS Collection 5.1 standard product, ‘Deep Blue’ over arid surfaces (Hsu et al., 2004, 2006) and ‘Dark Target’ over vegetated surfaces (Levy et al., 2007). Secondly, the ‘data-assimilation (DA) quality’ MODIS AOD (hereafter DA MODIS), which is an attempt to create a filtered and bias-corrected version of the MODIS Collection 5.1 ‘Dark Target’ data (Hyer et al., 2011). The MODIS sensors aboard the Terra and Aqua satellites are considered separately.

The comparisons with MODIS are at 1° horizontal resolution, while that with MISR is at 0.5°.
corresponding to the different resolutions of their standard products. Because the mutual overlap of all datasets on a given day is low, colocations are performed between SeaWiFS and each other dataset on an individual basis. To be considered for the comparison, grid cells in the daily products are only considered where both datasets contain at least 10 retrievals for the 1° comparisons, or 3 for the 0.5° comparisons, these thresholds being roughly equivalent relative to the grid size.

2.3 Definition of regions

![Region allocation for land AERONET sites](image)

**Fig. 1.** Geographical bounds of land regions used in this study for comparison of SeaWiFS AOD with other datasets.

Both sets of analyses consider over-land data globally, and also stratified into one of nine different regions, as shown in Figure 1. The choice of regions is somewhat arbitrary, and is not intended to follow geopolitical boundaries, but allows a fairly coarse examination of the retrieval under different atmospheric and surface conditions. For example, a generally low AOD and dense vegetation are found over much of eastern North America or Eurasia, but an arid surface and periodic dust storms are found in northern Africa and the Middle East. Nine regions, corresponding roughly with those often used in regional analyses of aerosol properties, were chosen as a compromise between isolating individual aerosol/surface regimes and retaining sufficient data volume in each to present a meaningful analysis.
3 Global comparison with AERONET data

3.1 Effect of QA

Considering data from all AERONET sites together, and restricting SeaWiFS data to QA=3 only, leads to joint histograms of SeaWiFS and AERONET AOD or Ångström exponent as shown in Figure 2, revealing a high level of agreement in spectral AOD. The Ångström exponent compares poorly, but if only cases of moderate or high AOD (\( \tau_{A,550} \geq 0.3 \)) are considered, the correlation improves. This is expected as in low-AOD conditions small uncertainties on \( \tau \) can propagate to large uncertainties on \( \alpha \) (Wagner and Silva, 2008), and similar behaviour is generally found in other satellite datasets (e.g. Levy et al., 2010). Some artefacts are visible in the distributions; namely, that the minimum permitted \( \tau_{550} \) is set to 0.02 for SeaWiFS for some surface types, and that \( \alpha \) is forced to 1 in SeaWiFS if \( \tau_{550} < 0.1 \) (due to a lack of information), and bounds are set on \( \alpha \) dependent on the aerosol microphysical model used for retrieval in a given area.

An important concept (Kahn et al., 2010, Levy et al., 2010, Sayer et al., 2012, and others) is the notion of expected error (EE); namely, what is the confidence envelope which describes the uncertainty on the SeaWiFS AOD? This can be estimated from the comparisons with AERONET, assuming that the AERONET data represent an unbiased and comparatively low-error measure of the true AOD. The goal is to define some function such that the absolute difference between SeaWiFS
and AERONET falls within this EE for one standard deviation (∼68 %) of the colocations, and two standard deviation (∼95 %) within twice this EE. The error ratio (ER) for an individual matchup is defined as the difference between SeaWiFS and AERONET AOD, divided by the EE.

The established over-land EE for MODIS Dark Target and MISR midvisible AODs are 0.05+0.15τA,550, and the greater of 0.05 or 0.2τA,550, respectively. An AOD-dependent component is linked to uncertainties associated with aerosol microphysical model assumptions, while an AOD-independent component is linked to factors such as uncertainties in surface reflectance modelling. Simulations and experience with SeaWiFS data suggest that the EE should be larger, as SeaWiFS is lacking in spectral resolution compared to MODIS, angular resolution compared to MISR, and spatial resolution compared to both.

Assessment of the set of matchups with QA=3 suggests that an appropriate set of spectral EE are 0.05+0.25τA,412, 0.05+0.20τA,490, 0.05+0.20τA,550, and 0.05+0.15τA,670, which are met by over 68 % of the points (Table 1). Dependent on wavelength, 90 %-95 % fall within twice the EE, indicating there are slightly more outliers than would be expected if these expressions of EE were true Gaussian measures of the retrieval uncertainty. Because the AERONET uncertainty is much smaller, it can be neglected for the estimation of EE. No EE is estimated for α; as Figure 2 shows, it is qualitatively clustered with the AERONET data for τA,550 > 0.3, although is not recommended for lower AOD. Additionally, for low aerosol loading, the uncertainty on AERONET AOD can itself be significant in calculating α (Wagner and Silva, 2008).

If the requirement for QA=3 pixels is relaxed, the number of comparisons increases, although the correlation and fraction of comparisons within the EE decreases (Table 1). This suggests that the SeaWiFS quality flags do provide information about the quality of the retrieval. The true decrease in quality with decreasing quality flag may be more extreme than noted here, as a primary reason for assignment of a low QA flag is suspicion of cloud-contamination. By definition the points in the AERONET comparison have passed cloud-screening for both the SeaWiFS and AERONET datasets, so the frequency of cloud-contamination in SeaWiFS retrievals is likely higher in the whole dataset than the subset with valid AERONET comparisons. For these reasons, only QA=3 data are recommended for general use, although QA=2 may also be useful if for a specific application a user possesses additional information such as auxiliary cloud masks. Only QA=3 data were used for the generation of available over-land SeaWiFS level 3 data products.

Finally, it is relevant whether or not restriction to QA=3 data introduces a sampling bias into the underlying distribution of AOD. Figure 3 shows histograms of the AERONET AOD at 550 nm, for the nine regions in Figure 1, for the colocations obtained by each different SeaWiFS QA threshold. Each region generally approximates a lognormal distribution (also noted by O’Neill et al., 2000 for individual AERONET sites), although peaks and widths differ. The Central/South America region has a longer positive tail, which is likely due to seasonal biomass burning aerosol observed at several of the sites (notably Abracos Hill, Alta Floresta, and Rio Branco). The histograms of AOD are very
Fig. 3. Histograms of AERONET AOD at 550 nm obtained from SeaWiFS-AERONET matchups. Each subfigure shows a composite from sites in different regions, as defined in Figure 1. Black lines show histograms for matchups with all SeaWiFS QA permitted, red lines those matchups obtained using QA=2 or QA=3 retrievals only, and green lines those matchups using QA=3 only.

similar for all QA thresholds, which suggests that restricting to only QA=3 SeaWiFS data does not cause a sampling bias in the ‘true’ distribution of AOD. The region with the least similarity between the QA=3 distribution and others is north-eastern Asia. The majority of the points in this region are from urban areas in China, or the Gobi Desert. In these cases it appears that restriction to QA=3 reduces the relative frequency of the lowest ($\tau_{A,550} < 0.05$) and highest ($\tau_{A,550} > 1$) AOD.

3.2 Effect of spatial averaging

A further question is whether the spatial averaging of SeaWiFS data is decreasing the apparent error, by averaging out noise in the data. To test this, a more restricted additional comparison was performed, using only SeaWiFS retrievals whose footprint included the AERONET sites directly (i.e. no spatial averaging) and requiring a tighter temporal coincidence of sampling (averaging within ±15 minutes rather than 30). The resulting sample size, correlations, and fraction within EE are shown in Table 1 for each QA threshold: statistics are very similar to the 25 km/30 minute case,

Table 1. Statistics of validation of spectral AOD with AERONET data, for different thresholds on the minimum SeaWiFS QA value permitted, and both area-averaged and direct colocations. $R$ is Pearson’s linear correlation coefficient.

indicating that retrieval noise is a minor component, i.e. most errors in a given region are likely systematic, linked to characterisation of surface and aerosol microphysical properties at that space and time, rather than radiometric. The tighter colocation criteria result in sampling decreasing by approximately half. Therefore, as the statistics of the comparison are similar, and the sample size double, the 25 km/30 minute comparisons will be used for the further analysis.

### 3.3 Dependence on AOD

Figure 4 shows the error in the retrieved AOD ($\tau - \tau_A$) binned as a function of $\tau_A$, with lines and shading to indicate different percentiles of the error distribution. For low AODs, the SeaWiFS data have negligible offset. The distribution of retrieval errors in these cases must be biased positive, as retrieval of negative AOD is not permitted. As AOD increases above about 0.5, at all wavelengths a negative bias of order 15% is observed. However, for the range of AOD in which the majority of data lie (typically 0.05-0.3, e.g. Figure 3), the SeaWiFS data have on average an offset of order 0.02 or less from AERONET. SeaWiFS reports lower $\alpha$ than AERONET for all AOD; as $\alpha$ is fixed at 1 for $\tau_{550} < 0.1$ in SeaWiFS, Figure 4 (e) suggests that 1.5-2 would be a more appropriate value in these conditions, to give a comparatively unbiased estimate.

One possible explanation for a low bias at high AOD is an underestimation of aerosol absorption. However, as TOA reflectance is not a linear function of AOD, heterogeneity of aerosol on a sub-retrieval scale could also be a factor, particularly close to strong sources (e.g. Alexandrov et al., 2004, Shinozuka and Redemann, 2011). Figure 5 shows TOA reflectance stored in the lookup tables used in the SeaWiFS AOD retrieval (defined as the TOA radiance normalised by the solar irradiance) for typical observing conditions at the AERONET site of Banizoumbou in central Africa. In this figure, solar and viewing zenith angles were taken to be 32°, and the relative azimuth angle 120°.
Fig. 4. Retrieval error (SeaWiFS-AERONET) as a function of AERONET AOD, for AOD at (a) 412 nm, (b) 490 nm, (c) 550 nm, (d) 670 nm; (e) Ångström exponent (as a function of AOD at 550 nm). In these, data are binned in order of ascending AOD, with a bin size of 500 matchups. In each plot, the red line shows the mean error, the solid black line the median, dotted black lines the 16th and 84th percentiles in that bin (i.e. the 68 % confidence interval), and the shaded grey area the bounds of the 2.5th and 97.5th percentiles (i.e. the 95 % confidence interval). Only points where QA=3 are included.

Fig. 5. Response of TOA reflectance to changes in AOD at (a) 412 nm, (b) 490 nm, and (c) 670 nm. Geometry, surface, and aerosol microphysical properties were taken as those typically encountered at Banizoumbou by SeaWiFS. The red line indicates the TOA reflectance as a function of AOD at that wavelength. The black dotted lines show the TOA reflectance for AOD of 0.5, 2, and 3.5. The black solid line shows the average of reflectances for AOD=0.5 and AOD=3.5, and the equivalent AOD for this reflectance.
Surface reflectances of 0.06, 0.1, and 0.2 at 412 nm, 490 nm, and 670 nm respectively were assumed, together with an absorbing aerosol model to represent biomass burning smoke. Suppose an AOD retrieval is performed on a pixel split in coverage evenly between a thick plume with and AOD of 3.5 and an elevated background AOD of 0.5. In this case, the area-weighted average AOD of the pixel would be 2. However, because of the nonlinearity, the TOA reflectance of this heterogeneous case does not correspond to the TOA reflectance of a homogeneous scene with an AOD of 2, and, presented with this reflectance, the algorithm would retrieve an AOD of 1.6, 1.7, and 1.8 at 412 nm, 490 nm, and 670 nm respectively. It is a philosophical point whether this should be considered an error or not, and potentially depends on the user’s desired application of the data, as the satellite would retrieve the radiative-average AOD rather than the spatial average.

Although this is a single example, it serves to illustrate the potential magnitude of such effects. At high AOD the increase in reflectance with AOD becomes smaller and the curves begin to flatten; the fact that the curvature is of this type suggests that, in a high-AOD case, a negative bias in satellite-retrieved AOD would be more likely than a positive bias. This will be an issue for other, similar retrieval algorithms, and it could be ameliorated in the future by sensors with higher spatial resolution, or assuming some degree of spatial heterogeneity in AOD (rather than homogeneity) in the radiative transfer calculations used in such algorithms.

![Graph](image)

**Fig. 6.** Retrieval error ratio (ER) at 550 nm, defined as the ratio of the retrieval error to the expected error, as a function of AERONET $\alpha$. Data are binned in order of ascending $\alpha$, with a bin size of 500 matchups, and only QA=3 points where $\tau_{A,550} > 0.3$ are considered. The lines and symbols are as indicated in Figure 4.

As $\alpha$ can be used as a first-order indication of aerosol type (e.g. Eck et al., 1999), Figure 6 examines the ER at 550 nm as a function of $\alpha_A$. Only points where $\tau_{A,550} > 0.3$ are used, both to ensure the utility of $\alpha_A$, and as the notion of a dominant aerosol ‘type’ is more meaningful when AOD is elevated significantly above typical background values. There is no clear dependence of ER on $\alpha_A$, suggesting that the underestimate of AOD for conditions of high aerosol loading occurs for all aerosol types, although the bounds of the 95% confidence limit become thinner (i.e. fewer extreme outliers) as $\alpha_A$ increases (corresponding to a more fine-mode dominated aerosol type).
3.4 Geometric dependence

Fig. 7. Retrieval error ratio (ER) at 550 nm, defined as the ratio of the retrieval error to the expected error, as a function of retrieval geometry. The top row shows points where $\tau_{A, 550} < 0.3$, and the bottom row $\tau_{A, 550} > 0.3$. Plots show dependence on (a,e) the solar zenith angle, (b,f) satellite (viewing) zenith angle, (c,g) relative azimuth angle, and (d,h) scattering angle. The bin size is $5^\circ$ for each angle, and only bins with 5 or more points are shown. The lines and symbols are as indicated in Figure 4. Dashed vertical lines show the angular range in which the central 68% of the data lie. Only points where QA=3 are included.

The ER is shown as a function of retrieval geometry in Figure 7, split into low-AOD conditions ($\tau_{A, 550} < 0.3$) where surface reflectance assumptions are expected to be the dominant source of uncertainty, and high-AOD conditions ($\tau_{A, 550} > 0.3$), where aerosol microphysical property assumptions are expected to dominate. The distributions of ER show some similarities in both groupings. When the atmospheric path length of reflected radiance is small (e.g. high-sun, near-nadir observations), the 95% confidence interval is wider, particularly on the positive-ER side. The contribution of the aerosol to the TOA signal will be smaller in these cases, and cloud detection also more difficult; further, this geometry is most frequently encountered in tropical regions, which more often have bright reflecting surfaces (e.g. the Sahara desert). The difference between the mean and median ER also becomes larger under these geometric conditions for low AOD, further indicative of stronger positive outliers.

A positive bias in AOD as the viewing geometry approaches backscatter is observable in low-AOD cases (Figure 7 (d)), but not high-AOD cases (Figure 7 (h)). This suggests that the surface reflectance models used in the SeaWiFS retrieval underestimate the ‘hotspot’ effect (e.g. Chen and Cihlar, 1997).
observed near the backscattering direction, and is therefore one avenue for improvement in future versions of the dataset. However, the bulk of the data lie at smaller scattering angles than those where this bias is largest.

Figure 7 (e) reveals an oscillation of ER with solar zenith angle, for $\tau_{A,550} > 0.3$. The reasons for this are at present unclear; examining the statistics on a regional basis (not shown) suggests the pattern is largely from matchups over the North Africa/Middle East, and South-East Asia regions, suggesting it could be linked to errors in dust or mixed dust/smoke phase functions at specific geometries. Finally, for both low-AOD and high-AOD cases, there is a small tendency for the ER to become more negative with increasing viewing zenith angle. However, the most dramatic angle-dependent effects appear to be associated with high-Sun conditions and retrievals close to the backscattering direction.

3.5 Temporal dependence

Fig. 8. Retrieval error ratio (ER) at 550 nm, defined as the ratio of the retrieval error to the expected error, as a function of time. Data are binned by year. The lines and symbols are as indicated in Figure 4. Only points where QA=3 are included, and only those sites with a long AERONET time series (listed in the text) are considered.

The 0.3 % radiometric stability of SeaWiFS calibration (Eplee Jr. et al., 2011) should translate into potential artificial trends in retrieved AOD smaller than 0.01 across the mission. The retrieval stability may differ from this if non-radiometric factors (e.g. applicability of assumptions made about surface reflectance or aerosol microphysical properties) changes through time. This can be assessed by examining the change in ER as a function of time in comparisons against AERONET. This approach was previously taken by Levy et al. (2010) when in validating the MODIS ‘Dark Target’ dataset. Only the subset of AERONET sites including data spanning at least a ten-year time period (Alta Floresta, Avignon, Banizoumbou, Beijing, Bondville, Bratts Lake, CART Site, Dakar, Dalanzadgad, GSFC, HJ Andrews, Ilorin, IMS METU-Erdemli, Ispra, Kanpur, MD Science Center, Mongu, Sede Boker, Sevilleta, Skukuza, Solar Village, Wallops) are used. Restricting to sites with a long time series helps to ensure that changes in the population of available AERONET sites between years do not influence the apparent trend in ER.
Figure 8 shows percentiles of the ER distribution as a function of year; there are no obvious trends. Performing a linear regression of the mean ER against year gives a gradient of $0.0112 \pm 0.0074$ (in units of ER per year); assuming a typical $\tau_{550} \approx 0.15$ (the mean and median AERONET values for the colocated data are 0.21 and 0.13 respectively) gives an estimate of a total drift of $0.0114 \pm 0.0075$ (in units of AOD) over the 13-year length of the dataset. Quoted trend uncertainties are the one-sigma uncertainty on the fit. These values are not significant at the 90% level, suggesting that if these long-term sites are representative of the SeaWiFS dataset as a whole, then there is not a statistically-significant linear change in the quality of the data with time, which is an important step in determining the utility of the dataset for trend analysis.

4 Regional comparisons

(a) Mean AERONET 550 nm AOD
(b) Fraction within expected error, 550 nm
(c) Correlation coefficient, 550 nm
(d) Median bias, 550 nm

The previous sections have established the utility of the SeaWiFS data on a global basis. However, due to differences in aerosol and surface properties (as well as observation geometry) in different parts of the world, it is logical to examine the data on a regional basis. This will aid the understanding of researchers interested in studies of a regional nature. To this end, Figure 9 maps various statistics
Table 2. Statistics of validation of spectral AOD with AERONET data. Sites are subset according to geographic region (Figure 1). $R$ is Pearson’s linear correlation coefficient.

Table 3. Statistics of comparison between colocated SeaWiFS daily-averaged AOD at 550 nm with that from other datasets. Only grid cells over land are considered. $R$ is Pearson’s linear correlation coefficient between the grid-box average values. The bias is the median bias between the daily average values, defined such that positive values indicate SeaWiFS AODs are larger. The scaled median absolute deviation of the difference between the two datasets is denoted $\sigma_{\text{med}}$.

Figure 10 shows the seasonal variability of SeaWiFS $\tau_{550}$, alongside the difference between SeaWiFS and the other satellite datasets considered. Images from MODIS Terra are omitted for brevity, as patterns were found to be very close to those from MODIS Aqua in most cases. The difference images have been resampled to $3^\circ$ horizontal resolution for ease of visualisation, and offsets between the datasets were largely observed to be spatially coherent on these scales. However, all statistics presented herein are calculated at full ($0.5^\circ$ or $1^\circ$) Level 3 resolution.

Table 3 shows the correlation, bias, and scaled median absolute deviation ($\sigma_{\text{med}}$) about the median difference in $\tau_{550}$, defined $\sigma_{\text{med}}(x) = \beta(x - \overset{\sim}{x})$, where $\sim$ indicates a median quantity and $\beta$ is a scaling factor. If the underlying distribution is Gaussian, then $\sigma_{\text{med}}$ is equivalent to standard deviation.
Fig. 10. Comparison between seasonal mean colocated SeaWiFS AOD at 550 nm and other satellite datasets. From left-right, columns indicate the seasons December-January-February (DJF), March-April-May (MAM), June-July-August (JJA), and September-October-November (SON). The top row shows (a-d) SeaWiFS seasonal mean AOD. Successive rows show the difference in seasonal mean AOD from colocated data between SeaWiFS and (e-h) MISR; (i-l) MODIS (Aqua); and (m-p) DA MODIS (Aqua).
for $\beta = 1.4826$, which is assumed here. This quantity is discussed further by Sayer et al. (2012). Note that it is not appropriate to consider a fraction within expected error for the inter-satellite comparisons. Reasons for this include the fact that none of the satellite datasets can be considered to provide a 'ground truth'; that some scatter is to be expected because of changes in aerosol loading between the overpasses of the different instruments; that there are differences in spatial sampling between the datasets (even though the methodology aims to minimise these); and that the expected error for individual retrievals from each dataset cannot be propagated into a Level 3 expected error, as it is uncertain which components of the retrieval error are a result of random error and which are systematic biases for any given point. These statistics are provided on a global scale (regional correlations are provided later), and reveal a high level of agreement, although a relative negative offset between 0.015 and 0.029 on a global basis.

The annual cycle of 550 nm AOD is shown in Figure 11 for each region. In this figure, the MODIS, DA MODIS, and MISR data are drawn from the set of colocated daily measurements described in Section 2.2. For simplicity, the SeaWiFS data are a simple multiannual (2006-2010) monthly mean in each region (as otherwise the plots would require one SeaWiFS line to correspond with each of

**Fig. 11.** Annual cycles of 550 nm AOD from the satellite datasets, for each region. Month names are abbreviated using their first letters, in order January-December.
the colocated datasets). Note that this means the spatial sampling may differ between the datasets. In particular, DA-MODIS lacks coverage over bright surfaces. This figure also illustrates the similarity between Terra and Aqua data, for the MODIS and DA MODIS datasets.

Finally, Figures 12-20 show joint histograms of SeaWiFS data against the other datasets used (AERONET, MISR, MODIS, DA-MODIS) for each of the nine regions described in Figure 1. A caveat here is, again, that the spatial extent of the area of each region which is sampled by AERONET is smaller than that covered by the satellites. The SeaWiFS/AERONET comparison are drawn from the set of matchups on an instantaneous basis (25 km/30 minute averaging), while the satellite inter-comparisons are from the colocated daily Level 3 data.

4.1 Eastern North America

![Scatter density plots for Eastern North America](image)

Fig. 12. Scatter density plots between SeaWiFS AOD at 550 nm and other datasets, for the Eastern North America region (Figure 1). (a) shows the comparison between SeaWiFS and AERONET for stations in this region. (b-d) show the comparison between colocated daily SeaWiFS and MISR, MODIS (Aqua), and DA MODIS (Aqua) data respectively. Correlation coefficients are shown above each panel.

This region is characterised by low AOD (mean $\tau_{550} \approx 0.1$ at all AERONET sites; Figure 9) and largely vegetated surfaces. Despite the low AOD, correlations between SeaWiFS and the other datasets are fairly strong, from 0.67 for SeaWiFS/MISR to 0.8 for SeaWiFS/AERONET. The fraction of SeaWiFS/AERONET matchups within EE is well in excess of 68% in this region. All datasets show a similar seasonality, with spring and summer peaks in AOD and a drop in autumn and winter (Figure 11). The offset between SeaWiFS and other datasets is small (within 0.02), spatially fairly
coherent (Figure 10) and shows seasonal variation (positive offset in JJA, negative in DJF and SON, variable in MAM) such that SeaWiFS exhibits a stronger seasonality in AOD. The consistency between sensors of the seasonal variability in the offset may reflect deficiencies in the seasonality of the surface reflectance assumed in SeaWiFS, as the low AOD means that the dominant uncertainty source is likely to be surface reflectance assumptions. For $\tau_{550} > 0.4$ SeaWiFS underestimates AOD relative to AERONET, MODIS, and DA-MODIS, although these cases account for a small minority of the data.

4.2 Western North America

Fig. 13. As Figure 12, except for the Western North America region (Figure 1).

The comparisons within this region are similar to Eastern North America, although part of the region is covered by bare (arid or mountainous) terrain, over which AOD retrieval is more challenging. For the region as a whole, 72% of SeaWiFS/AERONET matchups are within the EE. The arid parts of this region contain AERONET sites where SeaWiFS compares more poorly (notably Frenchman Flat and Rogers Dry Lake, both dry lake beds); SeaWiFS also tends to overestimate AOD relative to AERONET, MISR, and DA-MODIS for these arid areas. The negative offset of SeaWiFS against MODIS suggests MODIS may also be overestimating AOD for part of this region, which is consistent with the analysis of Levy et al. (2010). Seasonality is similar to Eastern North America, although here the spring peak in AOD is more pronounced, and is again generally consistent between sensors (Figure 11).
The AOD in the Central/South America region shows regional and seasonal diversity. High AOD is observed from seasonal biomass burning in the Amazon (AERONET sites of Rio Branco, Abracosh Hill, and Rio de Janeiro), which are reproduced well in all datasets, leading to a high level of correspondence. SeaWiFS underestimates AOD for the highest-AOD cases relative to AERONET, MODIS, and DA-MODIS, and overestimates relative to MISR, which is consistent with known validation results of these datasets (e.g. Kahn et al., 2010, Levy et al., 2010). Direct inter-satellite comparisons in the heart of the Amazon are sparse due to frequent cloud cover, with significant variability between mid-morning and early afternoon (Meskhidze et al., 2009), which limit sampling.

Away from biomass burning, lower AOD ($\tau_{A,550} \approx 0.2$) is found in urban AERONET sites in Mexico and Brazil. Although well-correlated, SeaWiFS has a low offset relative to AERONET for these sites. This offset is also observed when comparing with the other satellite datasets, and suggests an overestimation of surface reflectance in urban areas in this region. Finally, the southern part of this region has lower AOD still ($\tau_{A,550} < 0.1$); the correlation between SeaWiFS and AERONET is low for these sites, as the range of AOD encountered is comparable to the uncertainty on the retrieval, although the fraction within EE is large. The area around Buenos Aires is an exception to this, as SeaWiFS has a positive offset relative to the other datasets.

**Fig. 14.** As Figure 12, except for the Central/South America region (Figure 1).
4.4 Eurasia

Similar to Eastern North America, AERONET sites within Eurasia are largely found in suburban or agricultural regions with a low-AOD background, vegetated surfaces, and AOD peaks in spring and summer. Again, 84% of matches with AERONET are within the EE. The offset between SeaWiFS and other datasets again varies seasonally within the region, generally positive for the more vegetated parts and negative for the less vegetated parts, but is typically of order 0.02 or less. It is most pronounced in springtime, where SeaWiFS AOD is higher than the other satellites by up to 0.05, but otherwise the seasonality of AOD tracks well. This region contains almost 25% of all global matches between SeaWiFS and AERONET, so weighs heavily in the global statistics.

4.5 North Africa/Middle East

The aerosol burden in this region is largely composed of wind-blown mineral dust (with particular hotspots in the Bodélé Depression and western Sahara Desert), with additional contributions from biomass burning and anthropogenic emissions (Prospero et al., 2002, Knippertz and Todd, 2012). The majority of the surface is bare and bright, although the Sahel and savannas towards the southern end are more vegetated, as are some coastal portions. It should be noted that coverage of DA-MODIS is particularly sparse in this region, as the DA-MODIS dataset is drawn only from the ‘Dark Target’ MODIS product, which lacks coverage over bright surfaces (as noted in Section 2, ‘Deep Blue’ data provide coverage in arid regions in the standard MODIS product). Retrieval of
AOD from satellite data is challenging in this region due to the bright surfaces, mountainous terrain, complicated aerosol microphysical properties (e.g. Kalashnikova et al., 2005, Dubovik et al., 2006), and remoteness of locations meaning that many parts of the region are not well-covered by ground measurements (Figure 9). Because of the sampling issues, interpretation of the seasonal cycle in this region is difficult, although SeaWiFS, MISR, and MODIS all show peaks from May to July and a minimum from October to February, with a range of around 0.2 through the year.

Although well-correlated overall, at several of sites the proportion of SeaWiFS/AERONET matches within EE at 550 nm is 0.5 or less, in which cases SeaWiFS underestimates AOD. For the region as a whole, it is 0.58. Spatial patterns of the relative offset between SeaWiFS and other satellites vary seasonally, up to ±0.3 in some locations, and are not always consistent between the sensors. In general, for the highest AODs, SeaWiFS is higher than MISR, similar to MODIS, and lower than DA-MODIS, albeit with significant scatter in all cases. Examination of the surface reflectances retrieved by MISR and assumed by SeaWiFS in this region (not shown) reveals spatial patterns in close correspondence, which suggests that this is not the primary cause for regionally-varying offsets between the two. SeaWiFS AOD is lower than MISR over mountainous terrain; retrieval algorithm uncertainties related to elevation are likely to affect SeaWiFS more strongly than MISR (as the former relies more heavily on violet and blue wavelengths), so this may indicate a low-bias of SeaWiFS over mountains. SeaWiFS being higher than MISR for high AOD is consistent with known MISR validation results (Kahn et al., 2010). Comparing SeaWiFS and MODIS over the desert is less instructive because they share the ‘Deep Blue’ algorithm approach (although the recent application to
SeaWiFS introduces some updates over the algorithm applied in the Collection 5 MODIS product, particularly in terms of surface reflectance).

Due to the difficulty in accurate AOD retrieval here and sparseness of ground measurements, it is difficult to assess with confidence which dataset(s) are closest to the truth, and it is likely that without more advanced sensors and/or algorithms this will continue for the near future. Users are therefore advised to be aware of the differences between satellite AOD datasets in this region.

### 4.6 Southern Africa

![Graphs showing Southern Africa data](image)

**Fig. 17.** As Figure 12, except for the Southern Africa region (Figure 1).

Southern Africa is more influenced by biomass burning and less by mineral dust than the North Africa/Middle East region (Swap et al., 1996, Prospero et al., 2002, and references therein), although similar considerations about semiarid and elevated terrain, and complexity of aerosol microphysical properties, remain. Only 46% of SeaWiFS/AERONET matches at 550 nm are within the EE. The most poorly-performing sites in this region are biomass burning sites in Zambia, where SeaWiFS underestimates AOD by 0.1-0.2; it is possible that some of this is due to heterogeneity of aerosol near sources (e.g. Section 3). However, Figures 10 and 17 reveal that aside from at low-lying coastal regions, SeaWiFS AOD is generally negatively offset by between 0.05 and 0.25 compared to other satellites and AERONET even in low-AOD cases, which suggests an overestimation of surface reflectance. This could also indicate that the simple way in which terrain elevation is treated in the current version of the algorithm is inadequate in this region, where the majority of the terrain is at an altitude of 1 km or more above sea level. The same comments as made for seasonality of AOD in
Central/South America are applicable here.

### 4.7 North-Eastern Asia

AERONET sites in this region are split between fairly high-AOD regions in industrialised China, the Gobi Desert, and vegetation in Siberia; coverage is sparse for these latter two cases. On the whole, 72% of matches are within the EE. Performance at Irkutsk in Siberia is poor (50% in EE), but this is in a valley in mountainous terrain, and only 10 matchups were obtained. At Yulin, only 28% are within the EE; this is an elevated site, within a city surrounded by arid terrain. Again, at these sites, SeaWiFS is more likely to underestimate than overestimate AOD. The majority of points are from sites where the AOD is dominated by urban pollution and dust, at which the level of agreement is good, contributing to the correlation with AERONET of 0.86 for the region as a whole.

Due to seasonal cloud, snow cover, mountainous terrain, and bright desert surfaces, the majority of satellite data points in this region are in northern China and North/South Korea, with much of Mongolia, Japan, and Russia more sparsely covered. There is little net bias between SeaWiFS and MISR or DA-MODIS, although spatially-coherent biases in parts of the region contribute to scatter in Figure 18, particularly in the comparison with MISR. SeaWiFS has a more negative bias relative to MODIS, with the strongest outliers in the Taklimakan Desert. SeaWiFS exhibits a similar, but less negative, offset relative to MISR in this location. Unfortunately, there are no AERONET data available in the Taklimakan. SeaWiFS, MISR, and DA-MODIS all show a peak in AOD from March to May around 0.25, followed by AOD around 0.15 later in the year. This spring peak is strongly
enhanced in the MODIS data. MODIS and DA MODIS also have a secondary peak in December and January, absent from the other satellite datasets.

4.8 South-Eastern Asia

![Graphs showing correlation between AERONET and SeaWiFS AOD for South-Eastern Asia](image)

**Fig. 19.** As Figure 12, except for the South-Eastern Asia region (Figure 1).

Much of this region consists of agricultural land, interspersed with densely-populated cities, in which most of the AERONET sites are found. The aerosol loading is linked with large-scale meteorology, and seasonality differs between the Indian subcontinent and the eastern end of the region. In the Indian pre-monsoon (April-June), westerly winds blow dust across the Indo-Gangetic plain, where it is trapped by the Himalayas; the winter monsoon is associated with fog and thick haze from urban pollution and biomass burning aerosols (Prospero et al., 2002, Gautam et al., 2007, 2010, 2011). Over the Indo-China peninsula, intense biomass burning during the pre-monsoon (February-April), in combination with urban emissions, leads to an optically-thick absorbing haze layer (Carmichael et al., 2003, See et al., 2006, Gautam et al., 2012); monsoon rains during the summer washout much of the aerosol, and cloud cover limits SeaWiFS’s coverage. Similarly, near-persistent cloud cover means SeaWiFS coverage over Indonesia is sparse.

SeaWiFS is well-correlated with the other datasets in this region (Figures 9, 19), although only 61% of matches with AERONET are within the EE, as SeaWiFS has a low relative bias, for all AOD. Compared to the other satellites, SeaWiFS tends to retrieve lower AOD at those times and locations when very absorbing aerosols are present, which, in combination with the AERONET results, suggests the aerosol microphysical models used may be insufficiently absorbing. SeaWiFS
retrieves higher AOD than MISR over much of the Indo-Gangetic Plain in all seasons; the low bias of MISR with respect to AERONET and MODIS over parts of this region has previously been noted (Kahn et al., 2009, 2010). Over the region as a whole, SeaWiFS, MISR, and DA MODIS show AOD higher by 0.1-0.2 between March and August, relative to the September-February period. As in North-Eastern Asia, this peak is much stronger in the MODIS data.

4.9 Oceania

Fig. 20. As Figure 12, except for the Oceania region (Figure 1).

Although the correlation between SeaWiFS and other datasets is low in Oceania (Figures 9, 20), this is because the AOD is reported as persistently low by all datasets, such that the typical range of AOD encountered is similar to the typical spread of systematic biases over the region. AOD varies between around 0.04-0.05 (March-August) to 0.06-0.12 (September-February); offsets between datasets are larger during this second period. Overall, 71% of SeaWiFS/AERONET matches are within the EE. The one poorly-performing site is Birdsville, at which SeaWiFS overestimates AOD during all seasons, suggesting an underestimate of surface reflectance. Comparisons with MODIS and MISR reveal a negative offset of SeaWiFS in DJF and SON over the desert regions central and western Australia (of order -0.1); however, in comparison with the DA-MODIS dataset, the offset is near-zero in many locations, and data are absent in others. Unfortunately, there are no AERONET sites in these remote locations.
5 Conclusions

As the remote sensing of aerosol optical depth from space continues to be a challenging problem, it is useful that new datasets be validated against ground-truth data, and compared with other similar satellite datasets, to gain an understanding of their strengths and shortcomings. This study has performed such an evaluation for a new 13-year AOD dataset from SeaWiFS over land (the over-water component of the dataset is discussed in Sayer et al., 2012). The main results of the study are as follows:

– On a global basis, 72% of comparisons between SeaWiFS and AERONET AOD at 550 nm had an absolute difference within the expected error of $0.05 + 0.2\tau_{A,550}$, when only data with the highest SeaWiFS quality flag (QA=3) are considered. The analysis suggests that restricting to QA=3 does not significantly affect the way the underlying distribution of AOD is sampled, and that there is not a significant change in the quality of the SeaWiFS data through the mission. Performance is similar for the other wavelengths at which AOD is retrieved.

– Performance tends to be better over vegetated, low-lying terrain with low and moderate AOD, such as found over much of North America and Eurasia. Performance tends to be worse for low-AOD conditions near backscattering geometries (notably for scattering angles greater than 170°), where SeaWiFS overestimates AOD.

– SeaWiFS tends to underestimate AOD for optically-thick cases of absorbing aerosol, although often this underestimate remains within the expected error.

– On a regional basis, the satellites tend to produce similar seasonality to each other, and to AERONET. Differences between the satellite data are generally consistent with the known characteristics of the datasets. Unfortunately, many of the regions where large offsets exist between the satellite datasets are remote and not well-sampled by AERONET (also noted by Shi et al., 2011).

In conclusion, the SeaWiFS record provides a useful complement to other satellite AOD datasets and is suitable for quantitative scientific analysis. It is recommended that users consider only those retrievals identified as QA=3 (which is automatically the case with the Level 3 products), in order to extract the most reliable data for analysis, and bear in mind the results of this study depending on the geographic region of the user’s desired application. Given the high quality of SeaWiFS calibration, it is hoped that through further algorithm development some assumptions related to surface reflectance and aerosol microphysical properties can be refined, improving the utility of future versions of the data.
