MODELING THE METEOROID INPUT FUNCTION AT MID-LATITUDE USING
METEOR OBSERVATIONS BY THE MU RADAR

ABSTRACT
The Meteoroid Input Function (MIF) model has been developed with the purpose of
understanding the temporal and spatial variability of the meteoroid impact in the atmosphere.
This model includes the assessment of potential observational biases, namely through the use
of empirical measurements to characterize the minimum detectable radar cross-section (RCS)
for the particular High Power Large Aperture (HPLA) radar utilized. This RCS sensitivity
threshold allows for the characterization of the radar system’s ability to detect particles at a
given mass and velocity. The MIF has been shown to accurately predict the meteor detection
rate of several HPLA radar systems, including the Arecibo Observatory (AO) and the Poker
Flat Incoherent Scatter Radar (PFISR), as well as the seasonal and diurnal variations of the
meteor flux at various geographic locations. In this paper, the MIF model is used to predict
several properties of the meteors observed by the Middle and Upper atmosphere (MU) radar,
including the distributions of meteor areal density, speed, and radiant location. This study
offers new insight into the accuracy of the MIF, as it addresses the ability of the model to
predict meteor observations at middle geographic latitudes and for a radar operating frequency in the low VHF band. Furthermore, the interferometry capability of the MU radar allows for the assessment of the model’s ability to capture information about the fundamental input parameters of meteoroid source and speed. This paper demonstrates that the MIF is applicable to a wide range of HPLA radar instruments and increases the confidence of using the MIF as a global model, and it shows that the model accurately considers the speed and sporadic source distributions for the portion of the meteoroid population observable by MU.

1. INTRODUCTION

The majority of extraterrestrial particles entering Earth’s atmosphere originate from the Sporadic Meteoroid Complex (SMC) and are in the mass range of $10^{-11}$ to $10^{-4}$ g (Ceplecha et al., 1998; Baggaley, 2002; Williams and Murad, 2002). These sub-millimeter sized meteoroids enter the atmosphere at speeds between 11 and 72 km/s (Close et al., 2002) and subsequently collide with air molecules, causing heating and ablation of the incoming particles, which releases both neutral and ionized atoms from the meteoroid as well as ionizes the surrounding atmosphere. As a result, meteoroids deposit large amounts of metallic atoms (e.g. Si, Na, Fe, K, and Ca) in the Mesosphere and Lower Thermosphere (MLT), mostly over the altitude range of 70 to 140 km (Janches et al., 2003; 2009; Vondrak et al., 2008), and provide the dominant source of metals associated with many mesospheric layer phenomena (Plane, 2003). Moreover, similar ionized layers have been observed in other planetary atmospheres (e.g. at an altitude of approximately 90 km on Mars, 120 km on Venus, and 550 km on Titan; Kliore et al., 2008; Patzold et al., 2005, 2009; Withers et al., 2008).

There are various types of ionization regions associated with the meteoroid, collectively referred to as the meteor, which are created throughout the particle’s atmospheric entry
process (Janches et al., 2003). In particular, there is a relatively small plasma region surrounding and moving with the meteoroid, known as the meteor head echo (Janches et al., 2000; Close et al., 2002). High Power Large Aperture (HPLA) radar systems efficiently detect this target and have been extensively used over the past decade for various investigations that address issues related to plasma physics, space and solar system sciences, and astronomy (Janches et al., 2008). These instruments are capable of determining the meteoroid’s range and range rate with high precision, and in some cases, the object’s position and velocity vectors may be calculated, thus allowing for the estimation of orbital properties (Chau and Woodman, 2004; Sparks et al., 2010; Kero et al., 2011). HPLA systems are also effective at detecting the evolution of these quantities along the meteor path, and thus, they enable the study of various physical processes regarding the meteoroid mass loss mechanisms through either the dynamic or scattering behavior of the meteor (Close et al., 2004; Janches et al., 2009).

The Meteoroid Input Function (MIF) is a model developed to provide a global view of the diurnal and seasonal variations of the incoming meteoroid flux with the purpose of better understanding its relation to atmospheric phenomena in the MLT (Janches et al., 2006; Fentzke and Janches, 2008; Fentzke et al., 2009). The MIF assumes that the sporadic meteoroid population is distributed among the six known apparent sources: the North and South Apex, the Helion and Anti-Helion, and the North and South Toroidal (Jones and Brown, 1993; Taylor, 1997; Taylor and Efford, 1998). By assuming a global meteoroid mass input into the atmosphere (Ceplecha et al., 1998) and using Monte Carlo simulation techniques to assign an origin and speed to each modeled particle in agreement with the observed properties of the SMC apparent sources, the MIF predicts the overall meteoroid input to the MLT at any location on the Earth at any time of year and time of day. In order to
validate the simulations with observations, the model also produces meteor detection rates of
a particular HPLA system for a specified time and location. For this, considerations on
sensitivity limitations of the specific HPLA instrument are utilized in order to characterize
the portion of the incoming meteoroid population that is detectable by the specific radar
(Close et al., 2005; Janches et al., 2008). An example of the large difference in distribution of
meteor detections that can arise from using different observing instruments is shown by the
meteor studies conducted with the 430 MHz Arecibo Observatory (AO) radar in Puerto Rico
(−18°N) and the 440 MHz Poker Flat Incoherent Scatter Radar (PFISR) in Alaska (−67°N),
in which both systems operate at a similar transmitting power and frequency yet have
different aperture (Fentzke et al., 2009). The difference in radar aperture yields a considerable
difference in detection sensitivity, and thus, there is a significant difference in the spectrum of
meteoroid mass and velocity that each radar system is capable of observing. In addition, there
is an extreme difference in geographic latitude between the two radar locations, which causes
a difference in the portion of the SMC that each radar system observes. Nonetheless, the
meteor detection rate of both HPLA systems and the seasonal and geographical variability of
the incoming meteoroid flux were successfully captured by the MIF (Fentzke et al., 2009).

In order to better assess the accuracy of the MIF and improve the model as needed, further
comparison to meteor observations conducted by additional radar systems is necessary. In
particular, utilizing systems with different transmitting power and frequency improves the
confidence in the modeling of the physical considerations that determine radar sensitivity.
For that purpose, this paper presents the simulation of meteor observations obtained with the
46.5 MHz Middle and Upper atmosphere (MU) radar in Japan, offering the opportunity to
validate the temporal variations modeled with the MIF at middle geographic latitude as well
as the radar sensitivity considerations at the VHF frequency range. Lastly, the results
presented here have the novel aspect that the MU radar system possesses the ability to obtain
directional information from the detected meteors through the simultaneous use of several
receiving channels, thus enabling the determination of the meteor radiant locations for the
particle detections. This allows for the validation of the assumptions made regarding the
sporadic meteor source and speed distributions used as inputs to the MIF.

A description of the meteor experiment conducted at MU is presented in Section 2. The
application of the MIF model and the characterization of the meteor detection sensitivity of
the MU radar system are addressed in Section 3. Section 4 presents the results of the
experiment by providing a comparison between the observed data and the model predictions.
Lastly, the conclusions and final remarks are discussed in Section 5.

2. MU RADAR METEOR OBSERVATIONS

The MU radar is located in Shigaraki, Shiga Prefecture, Japan, at a geographic mid-latitude
location (34.85°N, 136.10°E) and has been utilized for over a decade for various studies
involving meteor observations (Sato et al., 2000; Fujiwara et al., 2007; Kero et al., 2011). The
MU radar consists of 475 Cross-Yagi antennas arranged in a 103 m diameter circular array
operating in the VHF band at 46.5 MHz and transmits a peak power of 1 MW.

For the purpose of this work, meteor observations using the MU radar were conducted over 4
distinct 24-hour periods near the equinoxes and solstices (December 18-19, 2008, and March
20-21, June 18-19, September 24-25, 2009). These observation periods were specifically
scheduled with the purpose of observing both the diurnal and seasonal variations in meteor
activity at a mid-latitude geographic location. For the observations reported in this work, an
uncoded radar pulse of 64 µs was transmitted with an interpulse period (IPP) of 1.28 ms and
a sampling frequency of 2 µs (i.e., 300 m range resolution). This scheme allowed for the probing of the altitude range between 79.5 and 139.2 km. In addition, the MU radar possesses 25 receiving channels, enabling simultaneous reception with independent sub-sections of the antenna array and thus allowing for highly sensitive interferometric measurements (Hassenpflug et al., 2008). For the case of meteor detections, this provides the capability to determine the meteoroid’s vector position and velocity, which give orbital information for each detected event. For the observations presented here, however, only 4 receiving channels were utilized, but nevertheless interferometric capability was still maintained (Nishimura et al., 2001).

Figure 1 shows an example of a meteor event observed during the March campaign and summarizes the identification and analysis technique utilized. Figure 1a (upper left) shows the Range-Time-Intensity (RTI) plot from the signal recorded by one of the receiving channels (see Figure 1 in Nishimura et al., 2001). The rectangular shape of the meteor head echo is due to the transmitted pulse shape (Sparks et al., 2009). Figure 1b (upper right) shows the Signal-to-Noise Ratio (SNR) of the same event. The overall ‘bell’ shape on the SNR curve is produced by the meteor traveling through the radar beam. It is important to note that the short-lived SNR enhancement occurring at approximately 0.03 s after the meteor is first detected is likely produced by the fast ablation of the alkali metals present in the meteoroid body (Vondrak et al., 2008; Janches et al., 2009). By cross-correlating the received raw voltages among the different channels, the phase differences between the received signals are obtained, as seen in Figure 1c (middle left). This information is then utilized to calculate the elevation and azimuth of each IPP during which the meteor is detected (Nishimura et al., 2001; Chau and Woodman, 2004; Sparks et al., 2010), displayed in Figure 1d (middle right). The line-of-sight velocity, which in this case is the vertical velocity, may be obtained from measuring either the rate of change of the meteor head echo altitude or the Doppler shift in the received signal. The absolute direction of the meteor is obtained from the
measured range, azimuth, and elevation, as shown in Figure 1e and Figure 1f (lower left and right, respectively). This provides a complete set of parameters to allow orbit determination.

The search and analysis of meteor events in the raw data follows the same methodology that has been applied to similar observations using the PFISR system (Sparks et al., 2010), where the only difference is in the manner in which the Doppler radial velocity is estimated. For the 440 MHz UHF operating frequency of PFISR, the Fast Fourier Transform (FFT) of the received signal in one IPP provides a sufficiently narrow spectrum to enable the accurate determination of the returned signal Doppler shift (Sparks et al., 2009). However, for the 46.5 MHz operating frequency of MU, the spectrum is as broad as the radar bandwidth. The Doppler signature is then calculated by applying a pulse-to-pulse correlation function between consecutive IPPs (Hagen and Farley, 1973; Mathews, 1976; Janches et al., 2000).

3. MODEL DESCRIPTION AND APPLICATION

3.1. The Meteoroid Input Function (MIF)

The MIF is an empirical model developed for the purpose of providing a global description of the diurnal, seasonal, and geographical variability of the meteoroid input in the upper atmosphere. This knowledge is required to better assess the relationship between the incoming flux and the chemistry and composition of the MLT (Janches et al., 2006; Gardner et al., 2011). The model, described in detail by Fentzke and Janches (2008), incorporates a global mass flux input into Earth’s atmosphere (Ceplecha et al., 1998) that is divided among the apparent sporadic meteoroid sources (Jones and Brown, 1993), each of which is represented as a Gaussian distribution of meteoroid speed and radiant. The North and South Apex sources are modeled collectively as approximately 33% of the meteoroids at 1 AU. The
remaining two-thirds of incoming meteoroids is divided among the other apparent sources, with the Helion and Anti-Helion sources each contributing nearly 22%, and the North and South Toroidal each providing 11% of the total flux. The speed distribution for each source is based on radar observations from various studies, using both HPLA and meteor radar systems. The Apex source is modeled as bimodal with approximately 80% of the particle speeds centered at 55 km/s and 20% centered at about 17 km/s (Janches et al., 2003; Sulzer, 2004; Janches and Chau, 2005). The remaining radiant sources (i.e., the Helion, Anti-Helion, and North and South Toroidal) are modeled as Gaussian with a peak at 30 km/s (Jones and Brown, 1993). Each of the apparent sources is modeled with the same particle mass distribution derived from the incoming mass-flux curve published by Ceplecha et al. (1998), which combines the results of several studies to estimate a global influx over the mass range of $10^{-18}$ to $10^{18}$ g and shows that the number of incoming meteoroids increases approximately exponentially with decreasing mass. The MIF models particles within the range of $10^{-11}$ to $10^{-4}$ g; however, for the purpose of this work the results presented only include particles in the mass range of 0.1 to 100 µg. Particles in this range ablate and produce electrons independent of speed (Bronshten, 1983; Vondrak et al., 2008), but the ability to detect them is strongly dependent on the radar system utilized (see Section 3.2). Tables 1 and 2 summarize the modeled distributions, organized by sporadic source, of the meteoroids that are visible over the geographic latitude of the MU radar. The columns in Table 1 present the mean and standard deviation of the speed, ecliptic longitude ($\lambda$), and ecliptic latitude ($\beta$) distributions for the sources. The ecliptic longitude is the angle of rotation about the ecliptic normal measured from the Earth-Sun direction, and the ecliptic latitude is the angle of rotation out of the ecliptic plane (i.e., the Sun is located at $\lambda=0^\circ$, $\beta=0^\circ$). Meanwhile, Table 2 provides the relative strength of contribution of each source, given as yearly and seasonal averages.

*Table 2: MIF modeled contributions of each sporadic source to the meteoroid population above the geographic location of MU.*

The MIF model provides the radiant location of each simulated particle, which is used to determine the sporadic source from which the meteoroid originates. The meteoroid source is determined by its proximity to the center locations of the six sporadic meteoroid apparent sources. The North and South Apex sources lie just above and below the direction of Earth’s velocity vector, with center points (λ, β) at (270°, 20°) and (270°, -20°), respectively. Likewise, the North and South Toroidal sources are above and below the Apex sources and are centered at (270°, 60°) and (270°, -60°), respectively. The Helion direction is towards the Sun (0°, 0°), and the Anti-Helion is in the opposite direction (180°, 0°). In the MIF simulations, the apparent source center that is closest to the particle radiant is considered to be the source of the particle and is the basis for determining the statistical distributions associated with each source presented in Tables 1 and 2.

### 3.1.1. MIF Diurnal Rates of Meteoroid Areal Density

The predicted rate of meteoroid counts per unit area, referred to here as the meteoroid areal density, at the MU radar latitude during the specified observation times is shown in Figure 2.
It is important to note that the rates presented in the figure do not represent detected events but instead incoming particles in the mass range 0.1-100 µg that form meteors at the specified geographic location (i.e., a meteor is formed but the MU radar may not detect it), assuming that the total meteoroid mass input is that given by the MIF and reported by Ceplecha et al., (1998). From the panels in the figure, it is evident that there is a seasonal variability of the meteoroid areal density in both the total number and shape distribution of the diurnal rate. As expected, the peak of the daily meteoroid flux occurs during the autumnal equinox since this is when the Apex sources reach their highest elevation in the Northern Hemisphere sky. Conversely, the daily minimum occurs during the spring equinox when the highest elevation that the Apex sources reach during the day is lowest, with a large portion of the South Apex never reaching an elevation higher than the local horizon (Fentzke and Janches, 2008). In addition, when comparing the observation times of the winter and summer solstices, it can be seen that for the December period there is a sharper increase in the number of meteoroids in the early morning, while during the June period there is a steeper decrease in meteoroid activity in the late morning and early afternoon. This is due to the changing orientation of the Helion and Anti-Helion sporadic sources during the year with respect to the MU radar location, which is significant in determining the amount of activity around local midnight and noon. In December, the Anti-Helion radiant reaches higher elevation than the Helion in the Northern Hemisphere sky; whereas in June, the situation reverses, introducing seasonal variability around the midnight and noon periods (Janches et al., 2006). In general however, at mid-northern latitude the simulated seasonal effects on the meteoroid input are not as pronounced as they are at higher latitudes (Janches et al., 2006; Fentzke et al., 2009; Sparks et al., 2009). The peak rate for meteoroids in the 0.1 to 100 µg mass range at the seasonal maximum (i.e., autumn) is estimated to be approximately 16 meteoroids/km²/min, compared to about 11 meteoroids/km²/min during the minimum activity period (i.e., spring).
Finally, it is clear from Figure 2 that for each day there is a predicted peak in meteoroid activity at 6:00 am, local time, when the Apex reaches its highest point in the sky relative to the observer (i.e., the MU radar). The minimum in meteoroid areal density occurs at 6:00 pm for all observing periods due to the fact that most of the sporadic sources are below the local horizon at this time of day. Since the meteor observations conducted with MU are taken over the 4 different simulated 24-hour periods, it is expected that the features evident in the modeled diurnal variation of meteor activity will be prominent in the observed data. This analysis is presented in Section 4.2.

3.1.2. MIF Modeled Distributions of Meteoroid Speed and Radiant

In addition to the rate of meteoroid areal density, the simulated radiant and speed distributions for the incoming meteoroids are presented in Figures 3 and 4, respectively. The radiant maps given in Figure 3 show the modeled meteoroid radiant in terms of ecliptic longitude ($\lambda$) and latitude ($\beta$) and represent the point in the sky that the meteoroids enter into a hyperbolic geocentric orbit (Jones and Brown, 1993). The radiant angles are defined as in Section 3.1, where the ecliptic longitude is the angle of rotation about the ecliptic normal measured from the Earth-Sun direction, and the ecliptic latitude is the angle of rotation out of the ecliptic plane (i.e., the Sun is located at $\lambda=0^\circ$, $\beta=0^\circ$). The plots in Figure 3 are oriented such that the center point corresponds to the Apex direction (i.e., the direction of Earth’s velocity relative to the Sun, $\lambda=270^\circ$, $\beta=0^\circ$). The locations of the six sporadic meteoroid sources are also displayed in the figure as ellipses, with the coordinates as specified in Section 3.1. The North and South Apex sources lie just above and below the figure center point, respectively. Likewise, the North and South Toroidal sources are above and below the respective Apex sources. To the left of the Apex is the Helion direction, and the Anti-Helion
is symmetrically opposite the Helion source about the Apex. Note that contributions from all of the sporadic sources are considered in the MIF and are clearly visible in Figure 3.

It is important to note, once again, that the distributions presented in Figures 3 and 4, also summarized in Tables 1 and 2, are the results from the MIF previous to taking any consideration of the detection capability of the MU radar system. From these results it can be derived that, as expected, the Apex sources provide approximately 33% of the modeled meteoroids in the 0.1 to 100 μg mass range, while the majority of the input is provided by the other sporadic enhancements. This is evident from the dominant peak in Figure 4 at approximately 30 km/s, as opposed to the secondary peak at 55 km/s, indicating that the majority of particles have the expected speed of the non-Apex meteoroids.

It is also evident from the radiant maps in Figure 3 that, given a constant global meteoroid input, the relative contributions of the South Apex, Helion, Anti-Helion, and South Toroidal sources to the local MLT show a seasonal variability. For example, the Helion and Anti-Helion sources provide a similar contribution of meteoroids to the MLT at mid-northern latitude in March and September. However, during December and June, one source contributes more meteoroids than the other. This is consistent with the relative steepness in the increase and decrease of expected meteoroid activity in the observation dates for each season, as shown in Figure 2 and discussed in Section 3.1.1. Additionally, the radiant distributions in Figure 3 highlight the overall meteoroid activity for each observation period. In September, when meteor activity is at its peak in the Northern Hemisphere, there are clear contributions from each of the sporadic meteor sources, and there is a very strong contribution from the North Apex. On the remaining dates, it can be seen that some portions of the radiant map are cut off from appearing over MU, and the relative strength of the Apex
sources is less than it is during September. The observation period in March demonstrates the inability to observe meteors with high southern ecliptic latitude radiant locations, and logically, this coincides with the time of year when meteoroid activity is at a minimum in the Northern Hemisphere. During this period, there is no contribution from the South Toroidal source and a reduced contribution from the South Apex source at mid-northern latitude. As in the case with the modeled variability of the diurnal rate of meteoroid areal density, these features are expected to be consistent with the MU observations, and the predicted and observed radiant maps will be compared to further validate the assumptions made by the MIF and the estimated input parameters used in the model.

3.2. MU Radar Characterization

When using instrumentation to conduct scientific experiments, it is necessary to characterize the biases and limitations introduced by the instruments being employed. For the case of meteor head echo observations with HPLA radars, it is inaccurate to generalize these system limitations over the entire radar class. Instead, each HPLA radar must be characterized and considered individually since the instruments are very different in comparison to each other (Janches et al., 2008), and furthermore, the characteristics of each system are dependent upon several radar parameters (e.g., operating frequency, aperture, transmitted power, etc.) (Close et al, 2002). A similar approach must be used for any radar system, including meteor radars such as CMOR and AMOR (Brown et al., 2008). In this manuscript, we characterize the observational capability of the MU radar in terms of the minimum detectable radar cross-section (RCS). The meteor RCS can be determined empirically from meteor measurements, assuming the meteor is a point target (Mathews et al., 1997; Close et al., 2002; Janches et al., 2008; Fentzke et al., 2009), defined by the radar equation as
In Equation 1, \( \rho \) is the observed range to the meteor, \( G \) is the radar antenna gain, \( \lambda \) is the signal wavelength, \( P_T \) is the radar transmitted power, and \( P_N \) is the noise power. The noise power is a function of the Boltzmann constant, \( k \), the noise bandwidth, \( B \), and the system temperature, \( T_{sys} \), and is given by \( P_N = kT_{sys}B \). For the MU system, these values have been reported by Kero et al., (2011) and are listed in Table 3.

\[
RCS = \frac{64\pi^3 P_N \rho^4}{P_T \lambda^2 G} \cdot SNR. \tag{1}
\]

*Table 3: Operational parameters for the MU radar.*

In total, 12,430 meteors were identified in the raw data collected during the four observing periods. Figure 5 presents the speed versus altitude distribution for all of the collected data. The distribution shows a substantial peak in the observation count over an altitude range of 95-105 km and at speeds between 50-60 km/s. This implies that, unlike the distributions shown in Figure 4, the vast majority of the detected meteors originate from the Apex apparent sources (Sekanina, 1976). Although this effect seems to be a typical result of HPLA observations (Close et al., 2000; Janches et al., 2003; Westman et al., 2004; Chau et al., 2007; Kero et al., 2011), the cause is different depending on the radar sensitvity (Janches et al., 2008; Fentzke et al., 2009).
The calculated RCS of the observed meteors by MU are shown in Figure 6. From the figure, a sensitivity threshold can be derived; that is, we can determine a value for which meteors with smaller RCS will not be detected (Janches et al., 2008). From Figure 6, the threshold is estimated to be approximately -18 dBsm for the MU radar. This detection limit is significantly higher (i.e. the MU radar is less sensitive) than the thresholds that have been determined on other HPLA radars that are operating at higher frequencies (Close et al., 2007; Janches et al., 2008; Fentzke et al., 2009). Additionally, Kero et al. (2011) reports much lower RCS values for MU observations conducted during a separate experiment, which are due to the different operating conditions of the MU radar system prevalent in each study. This highlights the necessity to assess the sensitivity characteristics of each radar system individually and for the specific operating parameters utilized; generalizing the radar characteristics to other systems and observational studies can lead to inaccurate results.

Once the radar RCS threshold is determined, the properties of the meteoroids that are observable by the MU system are estimated by applying a scattering model that considers the meteor head echo as a spherical target with Gaussian plasma density distribution (Close et al., 2004; 2005; 2007). Assuming that the incident signal wavelength is larger than the head plasma radius (i.e., the radar frequency is at UHF or below) and the incoming meteoroid is a solid sphere, the meteor RCS is calculated as a function of particle mass, speed, and ablation altitude for a given radar operating frequency, described in detail by Close et al. (2005; 2007). Shown in Figure 7 are the modeled results when applied to the MU radar system. In order to highlight the differences among HPLA radars, Figure 7 also shows the results for three additional HPLA systems used for meteor observations: the ARPA Long-range Tracking And Instrumentation Radar (ALTAIR; 160 MHz), Arecibo (430 MHz), and PFISR (440 MHz). The vertical line depicts the sensitivity threshold of the radar, which is
determined for MU using the observed data presented in Figure 6 and for the other radar systems using similar methodology presented in previous studies (Close et al., 2007; Janches et al., 2007; Fentzke et al., 2009). According to the model, particles with RCS values that are to the right of the sensitivity threshold in Figure 7 will be detected by the respective radar, while meteoroids with RCS to the left will not produce a strong enough signal to be detected (Janches et al., 2008). In comparing the sensitivity limits of the different instruments, some important conclusions can be made. First, the RCS of a meteoroid with given mass and speed is highly dependent on the radar operating frequency. This dependence scales approximately as \( f^2 \) for meteor head echoes and \( f^6 \) for meteor non-specular trails, where \( f \) is the radar operating frequency (Close et al., 2008). Second, the sensitivity threshold varies greatly among the different HPLA systems. The MU radar, operating at 46.5 MHz, has a threshold at approximately -18 dBsm, which is much higher than the threshold of the 430 MHz Arecibo system, for example, at approximately -90 dBsm (Janches et al., 2007; Fentzke et al., 2009). Thus, it is clear from Figure 7 that the HPLA radar systems observe significantly different portions of the sporadic meteoroid population, and the unique biases of the particular instrument being utilized must be characterized in order to appropriately assess the properties of the incoming particles. Lastly, it is to be noted that this RCS modeling technique has been utilized in previous studies to produce consistent estimates of meteoroid mass from simultaneous meteor head echo observations on VHF and UHF with the ALTAIR system (Close et al., 2005; 2007). Additionally, the application of the RCS sensitivity threshold to the MIF model has been shown to accurately predict meteor observations conducted at Arecibo and PFISR (Fentzke et al., 2009).

The RCS modeled results suggest that the MU radar efficiently observes meteoroids with masses on the order of 1 \( \mu \)g if they are moving with speeds greater than about 60 km/s. For
larger particles (~10 µg), detectable RCS values will be produced at lower speeds (~30 km/s). For masses greater than 10 µg, all particle speeds should produce meteors with RCS observable by MU. However, the occurrence rate for such objects will be much lower than that for the less massive particles (Ceplecha et al., 1998). This is supported by the observed meteor speed distribution shown in Figure 5, which indicates that the majority of meteors detected by MU have speeds within the range 50-60 km/s. This situation is much different when considering other radars, however. The Arecibo 430 MHz radar system, for example, is able to effectively observe meteoroids as small as 0.1 µg over almost the entire incoming speed range and can observe even smaller masses if the meteor speed is higher.

*Table 4: Minimum meteoroid speed required for radar detection as a function of meteoroid mass for several HPLA radar systems*

The speed thresholds of observable meteors for the MU, ALTAIR, Arecibo, and PFISR systems are listed in Table 4 for the range of meteoroid masses that is included in the MIF model for this study. Note that many of the meteoroid sizes included in the MIF simulation presented in Section 3.1 are only observable by the MU radar if the particles are traveling with speed greater than approximately 50 km/s. Moreover, particles smaller than 0.1 µg regardless of speed are completely undetectable by the MU radar when using this particular waveform. Table 4 highlights that, once again, one must be cautious about the misleading interpretations that may occur when observation results from a particular HPLA system are taken out of context or generalized to other HPLA radar systems (Hunt et al., 2004; von
Zahn, 2005). While the analysis of the MU radar shows that a 1 µg meteoroid will not be detected if its incoming speed is slower than 60 km/s, the same methodology shows that a particle of this mass will be observed at much lower speeds by separate, more sensitive HPLA instruments (Figure 7; Janches et al., 2008; Fentzke et al., 2009).

Understanding the instrument dependent selection bias is crucial to estimating the total input of meteoric material in the atmosphere from these observations. For example, Nesvorny et al. (2010; 2011) report results from a recently developed dynamical model of the Zodiacal Dust Cloud (ZDC). The model considers the orbital properties of comets and asteroids from the dynamical evolution of dust particles after ejection, and its results are constrained by Infrared Astronomical Satellite observations of the ZDC. The authors suggest that 85-95% of the continuous input of sporadic meteoroids comes from Jupiter Family Comets, with the remainder originating from the asteroid belt and Oort cloud comets. Additionally, this portion of the continuous input has mass in the range 1 to 10 µg and a mean speed of about 14 km/s, providing a global mass input of roughly 42x10$^3$ kg/d. Furthermore, the authors suggest that, due to their slow speed, most of the incoming particles will not produce significant ionization to be detected by radar systems, and thus, this large flux occurs largely undetected by ground-based instruments. A qualitative attempt to validate this conclusion using meteor radar observations by the Canadian Meteor Orbit Radar (CMOR; Webster et al., 2004) and the Advanced Meteor Orbit Radar (AMOR; Baggaley et al., 1994) is reported in Nesvorny et al. (2011). Additionally, the results presented in Figure 7 and Table 4 demonstrate that the MU system would not be able to detect the majority of particles entering the atmosphere at slow speeds with mass between 1 to 10 µg, and if indeed the population proposed by Nesvorny et al. (2010; 2011) exists, it would remain mostly undetected by this particular radar system. However, when considering the results given in Figure 7 and Table 4, it is evident that such a
meteoroid population would be detected by the Arecibo radar, and the ALTAIR and PFISR systems would be able to detect a significant portion of it. This implies that the speed distribution measured by the most sensitive HPLA radar systems would have to be dominated by slow particles, and yet this has not been observed to be the case.

4. COMPARISON OF THE OBSERVATIONS TO MODEL SIMULATION

Utilizing the MIF results to reproduce the meteor observations of HPLA radar systems has shown great agreement in previous work. This requires the implementation of methods to characterize the detection characteristics of the radar systems employed. Specifically, meteor observations made with Arecibo in Puerto Rico and PFISR in Alaska have been accurately modeled using the MIF together with the empirically determined RCS threshold of each radar system (Fentzke et al., 2009). Meteoroids with masses and speeds that coincide with a meteor RCS less than the sensitivity threshold of each instrument (Section 3.2) are considered undetectable and removed from the MIF output since the model predicts the total meteoroid presence without any consideration of specific observational biases (Section 3.1). The resulting distribution from applying this method represents the simulated meteors detected in each experiment. With both Arecibo and PFISR, the predicted meteor detection rate and radial speed distribution strongly agreed with the observed results. Furthermore, the simulations also showed strong agreements in the diurnal, seasonal, and geographical variability of these quantities. Additionally, the results show that even though the particular method of determining the RCS sensitivity limit of two unique HPLA radar systems represents a parameterization of a complex process that does not yet consider some effects (e.g. radar beam pattern or the latest ablation and electron production models), it nevertheless produces accurate results in predicting the overall observed meteor rates and speed distributions. In this section, the same methodology is applied with the MIF simulations
presented in Section 3.1 in conjunction with the RCS sensitivity results of the MU radar described in Section 3.2 in order to compare the model-predicted meteoroid properties with the meteor observations conducted at MU.

4.1. Meteoroid Entry Angle

A technical advantage for meteor observation that is available with the MU radar is its capability to perform interferometry, enabling the determination of the 3-dimensional position and velocity, and thus the orbit, of a meteoroid. Likewise, the zenith angle of the meteoroid trajectory can be obtained from the components of the velocity vector and is referred to here as the meteoroid entry angle. The observed entry angle distributions for the MU observation periods are shown in Figure 8. In the figure, an entry angle of 0° corresponds to a trajectory that is aligned with the local vertical (i.e. the meteoroid is travelling straight downward), while 90° corresponds to a horizontal velocity vector. A clear seasonal effect is evident in these distributions. As expected from previous work, the entry angle distributions are similar during the solstices, while during the equinox dates the angles are skewed in opposite directions from the solstice distribution. At the autumnal equinox, the majority of meteoroid trajectories are closer to vertical, while during the spring equinox the trajectories are more horizontal. These results are in agreement with previous observations, and the seasonal effects have been observed to be more pronounced at higher geographic latitudes (Janches et al., 2006; Fenzke et al., 2009; Sparks et al., 2010). This effect is due to the relative position of the apparent sources, in particular the Apex, with respect to the observer (i.e. the MU radar). Characterizing this distribution of meteoroid entry angle enables the construction of a more realistic picture of how the incoming meteoroid mass is deposited in the upper atmosphere and how it impacts the composition and chemistry of the mesosphere (Gardner et al., 2011). Additionally, the distributions presented in Figure 8 allow for the
estimation of a range of entry angles within which the incoming meteoroids detected by MU appear to occur. A similar methodology has been used in previous work employing MIF simulations, where meteoroids with radiant locations below 20° elevation from the local horizon appeared not to be observed with the respective radar systems (Janches et al., 2006; Fentzke and Janches, 2008; Fentzke et al., 2009). However, for the MU radar, the entry angle of each detected meteoroid can be calculated, and the range of observed entry angles can be empirically determined with more confidence. Additionally, the entry angle range can be estimated individually for each observation period to provide a more accurate description of the observation capabilities of the MU radar. In order to determine the entry angle range, the points where the number of observations with a particular entry angle is half of the number of observations of the most observed entry angle (i.e., the entry angle values in Figure 8 where the distribution crosses 0.5 on the vertical axis) are taken as the limits to the range. These angle ranges for the MU observation periods were determined to be: 33°-65° for March; 25°-60° for June; 17°-60° for September; and 20°-60° for December. The characterization of the MU radar entry angle range is necessary because meteoroids outside of this range appear in the MIF simulations, and these particles must be removed from the model in order to accurately estimate properties of the meteors detected with the MU radar system, such as the areal density rate, speed distribution, and radiant positions.

4.2. Meteor Areal Density Rate

In Section 3.2 the MU meteor observations were utilized to characterize the sensitivity of the radar system. For the purpose of this work, the mass-speed threshold presented in Figure 7 and summarized in Table 4 is used to determine which of the modeled meteoroids will be detected by the MU radar. As described in Section 3.2, meteoroids with mass and speed characteristics that are to the right of the RCS thresholds in Figure 7 are considered
observable by that particular radar system, which enables the determination of the minimum meteoroid speed that a particle with a given mass must have in order to be detected. All modeled meteoroids with a mass and speed that is below the detection threshold are removed from the MIF simulation of Section 3.1. In addition, meteoroids originating from a radiant that has an elevation angle outside the range of entry angles that are observed to produce the majority of the detections, as shown in Figure 8, are neglected from the simulated input. We note once again, that one must not generalize a particular mass-speed threshold to all HPLA radar systems. The sensitivity characteristics are only applicable to the specific radar instrument for which they were determined.

Comparisons between observed and predicted meteor areal density rates (i.e., the number of detected meteoroids per cross-sectional area per unit time) for the four observation periods are presented in Figure 9. It can be seen from the figure that there is very good agreement between the observed and predicted meteor rates. Note that these numbers are not normalized and represent actual detection rates. Moreover, these results indicate that even though the simulated detection threshold methodology is somewhat simplistic, it accurately reproduces the observations, which peak between 0.2-0.3 meteors/km$^2$/min for each of the observation periods. Further development of the sensitivity threshold analysis is ongoing and will include head echo electron density profiles derived from differential ablation models (Vondrak et al., 2008; Janches et al., 2009) as well as a more accurate representation of the radar beam shape (Dyrud and Janches, 2008).

As expected, for each observing period, the observed and predicted rates of areal density peak around 6:00 am, when the Apex reaches its highest elevation. The seasonal minimum rate of meteor areal density occurs in March (i.e. spring), resulting in a significantly lower meteor
rate than the other observing periods. This is also predicted by the model and is consistent with the overall trend seen in the modeled meteoroid input at the MU system’s geographical location, illustrated in Figure 2. Note that the maximum rate of observed meteors occurs in December and not in September, which is unlike the MIF input that predicts the maximum rate of activity during the autumn. A similar trend was reported in Arecibo observations (Janches et al., 2006). One characteristic of the MIF is that it assumes a uniform meteor input throughout the year, and these results indicate that this may not be the case. For some times of year, the overall sporadic meteoroid background input may be larger than at other times. Regardless of these unexpected trends, in general the MIF results shown in Figure 9 accurately predict the seasonal variations observed by the MU radar when also accounting for the sensitivity characteristics of the system. This highlights the ability of the model to determine the input of meteors and the corresponding radar-dependent portion of the meteoroid population that is detectable. These detection biases and limitations of the particular radar system can introduce additional diurnal and seasonal variations to the observed data, which must be characterized accurately in order to properly model the impact of the sporadic meteoroid population in the upper atmosphere. For example in Figure 9, the December and June observations show skewed peaks in the meteor activity around the time when the elevation of the Apex is highest (i.e. 6:00 am local time). There are more meteors in the early morning in December and in the late morning in June. This is also captured in the MIF simulations (Figure 2) and is due to the orientation of the radar location with respect to the Helion and Anti-Helion sporadic sources at these times. This effect becomes more pronounced when the detection characteristics of the MU radar are applied to the MIF results. This causes the skewed peaks in the predicted detection rates evident in Figure 9 for December and June as well as the double hump structure in March and September. These same features have been observed at lower latitude by Arecibo (Janches et al., 2006). In
December, the maximum elevation of the Anti-Helion source is higher than that of the Helion, and thus, more Helion originating meteoroids will be below the elevation threshold (Section 4.1) and rejected by the model. This causes a dip in the late morning detections in December. The reverse is true in June, causing the dip to occur in the early morning. The double hump in the detections during March and September are due to the position of the Apex sources in the sky. In September, the Apex is better visible in the Northern Hemisphere, and so the effect is more pronounced, as more of the Apex meteoroids are above the maximum elevation that tends to be observed, as represented in Figure 8.

The major difference between the model predictions and the radar observations is the overestimate by the model of the meteor areal density rate in the late morning and early afternoon for three out of the four observing periods. During these three periods, the modeled downward slope in areal density rate shown in Figure 9 appears to be consistent with the downward slope in the observed rate, but the observations start to decrease approximately an hour before the model predictions. Further analysis is required to determine the cause of this difference between the MIF model results and the observations. Nonetheless, these results show that the application of the MIF model together with the parameterization of the particular radar system used for the observations accurately captures the seasonal and diurnal variations in detection rate at mid-latitudes as it has for equatorial and polar latitudes using Arecibo and PFISR, respectively (Fentzke et al., 2009). In addition, these results demonstrate that the model can be applied to much lower radar operating frequencies than have been used in previous work.
4.3. **Meteor Speed Distribution**

An important property needed to understand the impact of sporadic meteoroids in the MLT is the speed distribution of the incoming particles. It is crucial to understand the differences between the true input speed distribution and that which is observed by a particular radar instrument. For the case of head echo observations using HPLA radar systems, this has been a fiercely debated topic, mainly due to the tendency of generalizing the results of one particular system to the entire radar class (Close et al., 2007; Janches et al., 2008). The input speed distribution considered in the MIF model is discussed in Section 3.1.2 and shown in Figure 4. The observed results by the MU radar as well as the instrument-specific predicted distributions, which account for the radar detection biases, are shown in Figure 10. Since the MU radar observations utilize interferometry, the speeds given in Figure 10 are the magnitudes of the absolute velocity vectors of the detected meteoroids and not the line-of-sight components as presented in previous studies (Fentzke and Janches, 2008; Fentzke et al., 2009). From Figure 10, it is evident that there is remarkable agreement obtained between the observed and predicted distributions. During each of the observing campaigns, the observations are characterized by a dominant peak centered at approximately 55 km/s, which is also well reproduced by the model. This indicates that the observations are dominated by particles originating from the Apex sources and is consistent with the observed maximum in diurnal rate of meteor areal density during the time when the Apex is at its highest elevation, as shown in Figure 9.

Table 5 displays the mean and standard deviation in observed speed of the incoming meteoroids originating from each source. The determination of the meteoroid source for both the observed and modeled meteors was conducted in the same manner as the source determination of the MIF simulated particles described in Section 3.1. The table shows that there is good agreement in the predicted and observed speed distributions of meteoroids from the Apex sources, where the predicted mean speeds are within 3.5% and 15% of the observed speeds for the fast and slow components, respectively. There is a significant difference in the standard deviation of the fast component, however, where the predicted value is almost 50% lower than the observed value. This is also the case with the observed standard deviation in speed of the other sporadic sources. The predicted deviations are 50-70% less than the standard deviations observed by the MU radar system. Moreover, some unexpected results are shown in the table between the predicted and observed mean speeds for these sources. While the contributions of the Helion and Anti-Helion sources are shown to be significantly overestimated by the MIF simulations, the estimated mean speed of the meteoroids originating from these two sources agrees well with the observed values. However, this same agreement is not evident between the predicted and observed values for the Toroidal sources. As in the case of the Helion and Anti-Helion sources, the MIF simulations predict that the mean speed of incoming meteoroids from the Toroidal sources is approximately 35 km/s; whereas the observations show a mean speed of 48 km/s and 54 km/s for the North Toroidal and South Toroidal, respectively. However, since the Toroidal sources are relatively close to the Apex sources, it is likely that this result is due to a contamination on the Toroidal sample.
by particles originally belonging to the Apex sources (i.e., these particles originate from a radiant location where the distributions of the Apex and Toroidal sources overlap). These results suggest that better orbital constraints, increased statistics, and further analysis and modeling of the speed characteristics of the sporadic sources are required, particularly over the meteoroid mass range of 0.1 to 100 µg that the MU system observes.

As shown in Table 4, the minimum speed for a 1 µg meteoroid to be detected by the MU radar is 60 km/s, but for slightly larger masses the minimum speed threshold decreases rapidly. Since the mean speed of the Apex source occurs near this threshold speed and the modeled number of meteoroids increases exponentially with decreasing mass (Ceplecha et al., 1998), this means that the observations (and predictions) will be dominated by the smaller, faster particles. Some of the differences between the shapes of the observed and predicted distributions are likely introduced by the fact that small errors in either the mass distribution or the radar sensitivity model can lead to fairly large changes in predicted meteoroid areal density and speed. Finally, there also appears to be a small seasonal variation in the peak location and width of the speed distribution that will need to be incorporated into the model to improve the predictions. The seasonal variation is even more prevalent at the lower speeds due to the fact that the relative strength of the different sources is dependent on time of year. Uncertainties in the mass distribution and radar threshold at these lower speeds likely explain the differences between the modeled and observed distribution. Furthermore, there may also be errors in the modeled speed distribution of the non-Apex sources that account for these observed differences, particularly with the Helion source in which the predicted areal density rate at times associated with this source also showed slight differences. Nevertheless, these errors appear to be mainly higher order, and the general shape of the predicted speed distribution agrees with the observations very well and is
sufficiently accurate for practical purposes. One final note is that such differences were not evident in previous observations conducted with the Arecibo radar, which detects much smaller particles than MU (Janches et al., 2006; Fentzke and Janches, 2008). In particular, the AO system is able to detect particles with mass as low as 0.1 µg traveling at slow speeds. This indicates that the sporadic source characteristics are likely dependent on meteoroid mass.

4.4. Meteor Radiant Distribution

The advantage of performing interferometry measurements with the MU radar is that it allows for the determination of the meteoroid orbital properties and radiant location (i.e., the point in the sky in which the meteoroid appears to originate; Kero et al., 2011). Table 6 summarizes the predicted and observed contributions of the sporadic meteoroid sources to the MU meteor detections and includes the radar-specific sensitivity characteristics, as discussed in Section 3.2. Once again, the determination of the observed and modeled meteoroid sources used the same methodology as described in Section 3.1. The table shows that the MIF model obtains strong agreement with the observations when the radar detection characteristics are taken into account. The strong effects introduced by the sensitivity of the MU system are further evident when comparing these results to the modeled input source contributions listed in Table 2. As discussed in Section 3.1, for meteoroids with masses in the 0.1 to 100 µg range, the Apex sources collectively contribute approximately 33% of the MIF model input, while the remaining 67% originates from the other sporadic sources, mostly from the Helion and Anti-Helion. However, as summarized in Table 6, the Apex contributes approximately 77% and 87% of the predicted and observed meteors, respectively, that are detected by the MU radar. While there is a substantial difference between these two values, both the predicted and observed contributions indicate that the vast majority of the MU-
detected meteors originate from the Apex sources, with the remaining sporadic sources representing a minority of the detections. The results in Table 6 show that the modeled contribution of the Helion and Anti-Helion sources is overestimated significantly, with approximately 20% of the detections predicted to come from these two sources collectively and only about 5% of the observed meteors attributed to them. Furthermore, while the modeled and observed contributions of the North Toroidal source agree strongly, this source is the secondary contributor to the meteors observed by MU yet is predicted to be only the fourth strongest sporadic source by the MIF simulations.

Table 6: Modeled and observed contributions of the sporadic sources to the meteoroid population detected by the MU radar system.

Figures 11 and 12 display the predicted and observed radiant distributions, respectively, for the meteors detected by the MU radar during the four observation periods, which are also summarized in Table 6. The coordinates in these figures as well as the location of the apparent sources are the same as in Figure 3 and described in Section 3.1.2. While it is more difficult to visually compare the meteor radiant distributions than it is the distributions of meteoroid areal density rate and speed due to the fact that the predicted and observed radiant distributions are plotted separately and span an additional dimension, some important
statements can nevertheless be made. In both the modeled and observed distributions, it can be seen that, as expected, the majority of the meteoroids originate from the Apex sources, particularly the North Apex. This is consistent with past studies as well as the observed variations in meteor areal density and speed (Sections 4.2 and 4.3) and agrees with the relative strength of contribution of the Apex sources given in Table 6. However, the predicted distributions of the Helion and Anti-Helion sources show stronger contributions than what was observed. This may suggest that the modeled strength and deviation of these sources is too high, or as discussed in Section 4.3, the mass and speed distributions of these sources may need to be reevaluated. Finally, the seasonal variation in the predicted meteor radiant distribution is clearly evident in Figure 11, where the portions of the ecliptic coordinates that are unobservable from the MU radar location are easily identified. While not as clearly visible in the MU meteor observations, the same seasonal variation is seen in the observed radiant distributions in Figure 12. The portion of the radiant map that is cut off in the predicted distribution is also free of observed radiant locations for each observation date. This shows the ability of the MIF to predict the general origin of meteoroids that are present above specific locations on the Earth at different times of year.

Similar to the discussion in Section 4.3, the results presented in Table 5 allow for some important comparisons to be made between the predicted and observed spatial distributions of each of the sporadic sources. The table provides the mean and standard deviation of the ecliptic latitude and longitude (defined in Section 3.1) of each source predicted by the MIF simulations and observed during the MU meteor observation periods. For each source, the observed mean ecliptic longitude ($\lambda$) agrees well with the predicted values. The largest difference is with the Helion and Anti-Helion sources, where the observed mean ecliptic longitude is approximately $5^\circ$ closer to the Apex than that which is given by the MIF results.
Likewise, the observed standard deviation in ecliptic longitude shows strong agreement with
the predicted values for each of the sporadic sources except for the Helion and Anti-Helion.
For these two sources, the observed distribution shows very little variation in ecliptic
longitude, while the model suggests a standard deviation of 15-18°. For ecliptic latitude, β,
the results are much different. The predictions and observations show excellent agreement in
both the mean and standard deviation of ecliptic latitude for the Helion and Anti-Helion
sources. However, for the remaining sporadic sources, the MIF simulations tend to place the
expected ecliptic latitude further north than what is observed by the MU radar. The model
also predicts a much larger standard deviation in ecliptic latitude than what was observed.
Clearly, more observations are required to improve the statistics in the weaker sporadic
sources, and additionally, further analysis is needed to shed light into the differences between
observed and predicted meteoroid speeds and radiant locations.

5. CONCLUSIONS

In this paper, the analysis of meteor head echo observations conducted with the 46.5 MHz
MU radar in Japan is presented. The observation periods were specifically scheduled with the
purpose of observing both the diurnal and seasonal variations in meteor activity at a mid-
latitude geographic location over four distinct 24-hour periods near the equinoxes and
solstices (December 18-19, 2008; and March 20-21, June 18-19, September 24-25, 2009).
The observed meteor properties were derived with the MIF model developed by Fentzke and
Janches (2008) in a similar manner utilized in previous meteor studies performed with the
Arecibo and PFISR systems (Fentzke et al., 2009). However, unlike previous studies, the
multiple receivers of the MU radar enabled interferometry measurements, allowing the
derivation, comparison, and validation of additional meteor flux characteristics. In order to
accurately compare the observations with the MIF, the sensitivity of the MU radar was
parameterized in order to determine the portion of the incoming meteoroid population that is
detectable by the radar system in terms of particle mass and speed. A comparison of the MU
radar parameterization with that of the HPLA radar systems ALTAIR, Arecibo, and PFISR
was also presented. This direct comparison of the sensitivity characteristics of the different
instruments demonstrates that each radar system detects a very distinct mass-speed portion of
the incoming meteoroid flux. This is a very important result in light of a recently developed
model of the Zodiacal Dust Cloud that predicts a large amount of meteoric mass in the
atmosphere that remains undetected by ground-based systems due to the slow speeds of the
incoming particles (Nesvorny et al., 2010; 2011). The results presented here show that
although this model would be consistent with the sensitivity characteristics of the MU radar,
more sensitive HPLA systems would be able to detect some portion of these slow particles.

Once the parameterization of the MU system’s sensitivity is applied to the MIF, the modeled
results show strong agreement with the observed seasonal and diurnal variations of meteor
areal density over the course of the observation periods. This result validates the accuracy of
the model at mid-northern latitudes. In addition, given the MU system’s VHF operating
frequency, the methodology used in this paper can, as a result, be applied to lower
frequencies than previously demonstrated.

Besides the diurnal rates, the MIF accurately reproduces the meteor speed distribution
observed by the MU radar. This supports the modeled input characteristics of the MIF for the
range of masses that are observable by the radar. As expected, the results show that the
majority of the meteor detections originate from the Apex sources and have masses as low as
1 µg for high speed particles (~60 km/s). While there is strong agreement in the distribution
at faster speeds, there is less agreement at the slower meteor speeds. This is probably due to
the fact that at the slow speeds the overall meteor counts are lower, and thus, the errors are more pronounced. However, it may also suggest that further analysis is required in the modeling of the meteoroid mass and speed distributions associated with the non-Apex sources and their relative strengths.

The MIF has also been shown to accurately predict the observed meteor radiant distributions. The seasonal variation in the origin of the observed particles is correctly modeled, and the relative strengths of the sporadic sources appear accurate. However, the distribution within each source seems to require more analysis as the MIF predicts a wider standard deviation in the radiant locations than what was observed. Nevertheless, the comparison of the model predictions to the MU observations greatly supports the validity of the MIF and its ability to be applied to different locations on the Earth at any time.

While the MIF has been shown to be very effective in predicting the properties of the meteoroid population that are observable with HPLA radars, it is important to note additional studies that are needed to enhance the strength of the model. First, the HPLA radars that have been used in MIF studies have all employed zenith pointing antennas. To improve the confidence in the MIF, it would be useful to compare its performance in predicting the meteor detections of radar systems that are observing different regions of the sky, such as those by the ALTAIR system, which has been used for meteor observations and has a steerable radar antenna (Close et al., 2000; Hunt et al., 2004). This would allow for better refinement of the sporadic source distributions. Second, the radar observations that have been compared to the MIF have been primarily from northern geographic locations. Although Janches et al. (2006) show agreement between an earlier version of the MIF and observations with the Jicamarca Radio Observatory (JRO) in Peru, it would be valuable to use the current
version of the model and compare it with additional meteor observations from the Southern Hemisphere. These studies can be performed not only with JRO but also with the Southern Argentine Agile MEteor Radar (SAAMER) in Argentina (Fritts et al., 2010), which is located at high-southern latitude. Such instruments would provide insight into differences in meteor activity over the Northern and Southern Hemispheres, particularly in regard to any asymmetry in strength between the North and South Toroidal sporadic sources. In addition, potential studies with SAAMER provide the opportunity to apply the MIF model to meteor radar observations of specular trails, which will greatly increase the confidence in the accuracy of the model, particularly for larger and slower meteoroid masses originating from the non-Apex sources.

6. ACKNOWLEDGMENTS

The MU radar system belongs to and is operated by the Research Institute of Sustainable Humanosphere (RISH), Kyoto University, Uji, Kyoto, Japan. SP, DJ, and JJS were supported under NSF Grants AST-0908118 and AGS-0525655 to NorthWest Research Associates, Inc. DJ is grateful to the Japanese Society for the Promotion of Science (JSPS) who supported his visit to the University of Kyoto, Japan, in 2009 under a short term fellowship, making the observations presented here and this study possible.
