Abstract:
As Neptune migrated, its mean-motion resonances preceded it into the planetesimal disk. The efficiency of capture into mean
motion resonances depends on the smoothness of Neptune's migration and the local population available to be captured.
The two strongest resonances, the 3:2 at 39.4 AU and 2:1 at 47.7 AU, straddle the core repository of the physically distinct
and binary-rich Cold Classicals, providing a unique opportunity to test the details of Neptune's migration. Smooth migration
should result in a measurable difference between the 3:2 and 2:1 resonant object properties, with low inclination 2:1s having
a high fraction of red binaries, mirroring that of the Cold Classicals while the 3:2 will would have fewer binaries. Rapid
migration would generate a more homogeneous result.
Resonant objects observed with HST show a higher rate of binaries in the 2:1 relative to the 3:2, significant at the 2\sigma level.
This suggests slow Neptune migration over a large enough distance that the 2:1 swept through the Cold Classical region.
Colors are available for only a fraction of these targets but a prevalence of red objects in outer Resonances has been
reported. We report here on ongoing observations with HST in cycle 19 targeting all unobserved Resonants with
observations that will measure color and search for binary companions using the WFC3.
