DISCOVERY OF SMALL-SCALE SPIRAL STRUCTURES IN THE DISK OF SAO 206462 (HD 135344B) : IMPLICATIONS FOR THE PHYSICAL STATE OF THE DISK FROM SPIRAL DENSITY WAVE THEORY

APJL, in press

ABSTRACT

We present high-resolution, H-band, imaging observations, collected with Subaru/HiCIAO, of the scattered light from the transitional disk around SAO 206462 (HD 135344B). Although previous sub-mm imagery suggested the existence of the dust-depleted cavity at r < 46 AU, our observations reveal the presence of scattered light components as close as 0″.2 (≈ 28 AU) from the star. Moreover, we have discovered two small-scale spiral structures lying within 0″.5 (≈ 70 AU). We present models for the spiral structures using the spiral density wave theory, and derive a disk aspect ratio of h ≈ 0.1, which is consistent with previous sub-mm observations. This model can potentially give estimates of the temperature and rotation profiles of the disk based on dynamical processes, independently from sub-mm observations. It also predicts the evolution of the spiral structures, which can be observable on timescales of 10-20 years, providing conclusive tests of the model. While we cannot uniquely identify the origin of these spirals, planets embedded in the disk may be capable of exciting the observed morphology. Assuming that this is the case, we can make predictions on the locations and, possibly, the masses of the unseen planets. Such planets may be detected by future multi-wavelength observations.

1. INTRODUCTION

Dynamical processes in protoplanetary disks such as turbulence or disk-planet interaction are important in understanding physical condition and evolution of disks, and planet formation processes. High resolution, direct imaging observations of circumstellar/protoplanetary disks can reveal non-axisymmetric structures, providing insight into such dynamical processes (e.g., Hashimoto et al. 2011).

Recent observations have identified a class of protoplanetary disks harboring tens of AU-scale holes/gaps at their centers: the so-called transitional disks. One well-studied system of that class is the rapidly rotating Herbig F star, SAO 206462 (HD 135344B, $F4Ve, d = 142 \pm 27$ pc, $M = 1.7^{+0.1}_{-0.2} M_{\odot}$, Müller et al. 2011). The observations of CO line profiles (Dent et al. 2005; Pontoppidan et al. 2008; Itoh et al. 2011) and stellar rotation (Müller et al. 2011) consistently indicate an almost face-on geometry ($i \approx 11^\circ$). The gap in the disk was predicted from the infrared (IR) spectral energy distribution (SED, Brown et al. 2007), and was subsequently imaged in sub-mm dust continuum at $\sim 0\farcs5 \times 0\farcs25$ resolution (Brown et al. 2009). Andrews et al. (2011) estimate the gap radius to be $\sim 40$ AU and the surface density within the gap to be $10^{-3.2}$ times smaller than that extrapolated from the outer disk. The gas in Keplerian motion surrounding the gap region is also imaged by CO lines (Itoh et al. 2011). The CO rotational line observations (Pontoppidan et al. 2008) and [OI] spectral line observations (van der Plas et al. 2008) indicate the presence of a gas disk in the vicinity (several AU-scale) of the star. SED modelling (Grady et al. 2009) and NIR interferometry (Fedele et al. 2008) indicate the presence of an inner dust belt, which is temporally variable (Sitko et al. 2012) and not coplanar with the outer disk (Benisty 2011, private communication). New imaging with high spatial resolution and sensitivity is required to understand the inner structures of the disk. The outer portions of gaps can now be resolved using 8-10 m ground-based telescopes at near infrared (NIR) wavelengths (e.g., Thalmann et al. 2010, for LkCa 15).

In this Letter, we present $H$-band polarized intensity (PI) observations of the disk of SAO 206462 down to $r \sim 0\farcs2$ ($\sim 28$ AU) scale at $0\farcs06$ ($\sim 8.4$ AU) resolution. Interior to the sub-mm resolved gap, we find spiral structures, indicative of dynamical processes. We use the spiral density wave theory to interpret the structure, and estimate disk's physical parameters.

2. OBSERVATIONS & DATA REDUCTION

2.1. HiCIAO Observations

SAO 206462 was observed in the $H$-band (1.6 $\mu$m) using the high-contrast imaging instrument HiCIAO (Tamura et al. 2006; Hodapp et al. 2008; Suzuki et al. 2010) on the Subaru Telescope on 2011 May 20 UT as part of Strategic Explorations of Exoplanets and Disks with Subaru (SEEDS, Tamura 2009). The adaptive optics system (AO188; Hayano et al. 2004; Minowa et al. 2010) provided a stable stellar point spread function (PSF, FWHM = $0\farcs06$). We used a combined angular differential imaging (ADI) and polarization differential imaging (PDI) mode with a field of view of $10'' \times 20''$ and a pixel scale of 9.5 mas pix$^{-1}$. A $0\farcs3$-diameter circular occulting mask was used to suppress the bright stellar halo. The half-wave plates were placed to four angular positions from $0^\circ$, $45^\circ$, $22.5^\circ$, and $67.5^\circ$ in sequence with one 30 sec exposure per wave plate position. The total integration time of the PI image was 780 sec after removing low quality images with large FHWMs by careful inspections of the stellar PSF.

2.2. PDI Data Reduction

The raw images were corrected using IRAF$^1$ for dark current and flat-field following the standard reduction scheme. We applied a distortion correction using globular cluster M5 data taken within a few days, using IRAF packages GEOMAP and GEOTRAN. Stokes $(Q, U)$ parameters and the PI image were obtained in the standard approach (e.g., Hinkley et al. 2009) as follows. By subtracting two images of extraordinary- and ordinary-rays at each wave plate position, we obtained $+Q$, $-Q$, $+U$, and $-U$ images, from which $2Q$ and $2U$ images were made by another subtraction to eliminate remaining aberration. $PI$ was then given by $PI = \sqrt{Q^2 + U^2}$. Instrumental polarization of HiCIAO at the Nasmyth instrument was corrected by following Joos et al. (2008). From frame-by-frame deviations, the typical error of surface brightness (SB) was estimated to be $\sim 5\%$ at $r \sim 0\farcs5$ when averaged over $5 \times 5$ pixels ($\sim$ PSF scale). Comparing different data reduction methods (frame selections and instrumental polarization estimates), we expect that the systematic uncertainty of the SB of $PI$ to be $\sim 10\%$.

2.3. Contemporaneous Photometry

Since SAO 206462 shows variability in NIR wavelengths (Sitko et al. 2012), it is important to take photometry simultaneously with disk observations. $H$-band photometry was obtained just before and after the disk imaging without the coronographic spot with the adaptive optics, by sixteen 1.5 sec exposures at four spatially dithered positions. An ND10 filter (9.8 $\pm$ 0.1% transmission) was used to avoid saturation. Using the MKO filter set, the $H$-band ($\lambda_{eff} = 1.615$ $\mu$m, FWHM = 0.29 $\mu$m, Tokunaga et al. 2002) magnitude was $8.96 \pm 0.07$ mag.

Broad-band $VRIJKH$ photometry was obtained on 2011 May 23-26, starting within 48 hours of the HiCIAO observation, using the Rapid Epeic Mount (REM) Telescope at La Silla, Chile (Covino et al. 2004). The REM $H$-band filter has $\lambda_{eff} = 1.65$ $\mu$m, FWHM = 0.35 $\mu$m: broader and displaced to longer wavelengths than the MKO filter. The observed data were reduced differentially using SAO 206463 (AOV). The IR excess due to the inner disk (Figure 1) was

---

average for the range observed in 2009-2011 (Sitko et al. 2012). No significant variation was observed during the 2011 May observations, except for the small long-term fading trend (6m = 0.08 ± 0.02 mag) over the observation period.

Figure 1 also displays spectra obtained with the SpeX spectrograph (Ravner et al. 2009) on NASA’s Infrared Telescope Facility (IRTF). The observations were obtained in the cross-dispersed (XD) echelle mode between 0.8 and 5.1 μm using a 0′′8 slit (R ~ 900) and calibrated using HD 129685 (AOV) with SpeXtool (Vacca et al. 2003; Cushing et al. 2004). The absolute flux calibration, to correct for light loss at the spectrograph slits, was accomplished in two ways: using photometry and wide-slit spectroscopy (see Sitko et al. 2012). The March SpeX data were normalized using the REM photometry, obtained in the days immediately after the SpeX observations, and when the star was photometrically stable. In July, SAO 206462 and the calibration star were observed with the SpeX prism using a 3′′0 slit, which, under good seeing and transparency conditions, produces absolute flux to ~ 5% accuracy. The REM photometry at H-band in May is ~ 0.25 mag brighter than the Subaru data. The Subaru photometry shows a low value even when considering the filter difference, suggesting that the outer disk is illuminated efficiently.

3. RESULTS
3.1. Spiral Structure

The SAO 206462 disk can be traced in PI from 0′′2 to ~ 1′′0 (28 – 140 AU), similar to the range imaged with HST/NICMOS (Grady et al. 2009), but with a factor of ~ 4 greater angular resolution. The total PI is 9.87 mJy ± 0.06% at 0′′2 < r < 1′′0, which is 0.6% of the stellar intensity. The total PI at 0′′42 < r < 1′′0 is 3.94 mJy ± 0.1% while the total intensity by HST/NICMOS F110W is 9.7 mJy (Grady et al. 2009). The average SB of PI at r = 0′′46 is ~ 6 mJy/arcsec², whereas the total intensity by HST/NICMOS F160W is 30 mJy/arcsec² (Grady et al. 2009). Given the NICMOS data uncertainties, the polarization fraction is ~ 20 – 40%, assuming no PSF halo in the HiCIAO data and no variable self-shadowing/illumination in the disk. Our measured polarization fraction is similar to that of HD 100546 (14% ± 10%, Quanz et al. 2011) and AB Aur (~ 25% – 45%, Perrin et al. 2009).

Figure 2 shows the PI image. The region interior to 0′′4 is not a void and we do not see clear structural evidence of the cavity wall in Andrews et al. (2011) model (R_{cav} = 46 AU ~ 0′′33). We see spiral arcs S1 (east) and S2 (south-west). The PI at the location of the spirals is ~ 30% larger than that extrapolated from the smooth outer profile (bottom of Figure 2). The brightest portions of the spirals roughly coincide with the bright thermal emission peaks at 12 μm (Marinés et al. 2011) and lie inside the ring noted by Doucet et al. (2006). It is also noted that we see a dip in PI in the north-west, probably due to the depolarization in the minor axis direction (see below), and that we do not see large-scale, localized shadow that might be cast by the inner dust belt if highly inclined relative to the outer disk.
3.2. Azimuthal and Radial Profiles

Here, we summarize the overall disk structure exterior to the spirals. Figure 3 (top panels) shows the azimuthal SB profiles at $r = 0''5$ and $r = 0''7$. At $r \geq 0''5$, SB has maxima around position angle (PA) $\sim 50^\circ - 60^\circ$ and $230^\circ - 240^\circ$. Since the polarization is maximized at $\sim 90^\circ$ scattering (e.g., Graham et al. 2007), it is implied that the disk major axis is at PA $\sim 50^\circ - 60^\circ$, comparable to estimates by CO observations: PA $= 56^\circ \pm 2^\circ$ by Pontoppidan et al. (2008) and $64^\circ \pm 2^\circ$ by Lyo et al. (2011). We adopt PA $= 55^\circ$ for the major axis and $i = 11^\circ$ for inclination (see Section 1). Our spiral model fitting results (the next section) are little affected even if we assume a face-on geometry.

From CO observations, it is known that the south-west side is receding (e.g., Lyo et al. 2011). Therefore, either the north-west or south-east side is the near side. We do not see an obvious forward scattering excess in the NIR image. However, since the spirals are typically trailing, it is inferred that the south-east is the near side.

Figure 3 also shows the radial $PI$ profiles along the major axis, which is roughly consistent with $r^{-3}$ in the outer part, indicating a flat (not highly flared) disk (Whitney and Hartmann 1992). The radial slopes vary as PA from $\sim -2$ to $\sim -4.5$ (fitting at $0''6 < r < 1''0$) or from $\sim -2.5$ to $\sim -5$ (fitting at $0''3 < r < 0''9$), with shallower slopes typically appearing in the minor axis directions. However, $r^{-3}$ is representative on average. This slope is observed in several
Spiral in the Disk of SAO 206462

FIG. 3. — Top: Azimuthal SB profile at \( r = 0.5 \) (left) and \( r = 0.7 \) (right) with PA measured from north to east. Bottom: Radial profile along the major axis. Position errors indicate the FWHM of the PSF. SB errors are estimated using frame-by-frame degradations.

other HAeBe disks (e.g., Fukagawa et al. 2010, for total intensity data), although HD 97048 disk exhibits a shallower slope (Quanz et al. 2012).

4. SPIRAL STRUCTURE MODELING

Among several features in the image, the most interesting one is the non-axisymmetric spirals. In order to understand them, we propose a model based on the spiral density wave theory (e.g., Lin and Shu 1964; Goldreich and Tremaine 1978, 1979; Ogilvie and Lubow 2002), assuming that NIR emission traces the disk surface density structure. With such a model, the spiral structures can be used to infer the disk temperature, independently of, for example, CO line observations.

The shape of the spiral density wave is determined by the location of the launching point (corotation radius \( r_c \)) and disk's thermal and rotation profiles. When the disk rotation angular frequency is \( \Omega(r) \propto r^{-\alpha} \) and the sound speed is \( c(r) \propto r^{-\beta} \), the shape of the wave far from \( r_c \) is given by

\[
\theta(r) = \theta_0 - \frac{\text{sgn}(r - r_c)}{h_c} \times \left[ \left( \frac{r}{r_c} \right)^{1+\beta} - \frac{1}{1+\beta} - \frac{1}{1-\alpha+\beta} \left( \frac{r}{r_c} \right)^{-\alpha} - \frac{1}{1+\beta} - \frac{1}{1-\alpha+\beta} \right]
\]

in the polar coordinate \((r, \theta)\), where \( h_c = c(r_c)/r_c\Omega(r_c) \) denotes the disk aspect ratio at \( r = r_c \) and \( \theta_0 \) gives the phase. Equation (1) well approximates the shape of the density wave given by the WKB theory (Rafikov 2002; Muto et al. 2011). When the spiral is excited by a planet in a circular orbit, its location is \( \sim (r_c, \theta_0) \). Equation (1) has five parameters, \((r_c, \theta_0, h_c, \alpha, \beta)\).

Two non-axisymmetric features, S1 and S2, (Figure 4) are identified as follows. First, local maxima in the radial SB profiles normalized by \( r^2 \) (to take into account the dilution of the stellar flux) are traced at every 1° step with data at \( 170^\circ < \text{PA} < 360^\circ \) (S1) and at \( 50^\circ < \text{PA} < 190^\circ \) (S2). The points near the minor axis (PA \( \sim 325^\circ \)) are excluded because the structure there may be affected by depolarization. The points at PA > 200° (S1) and PA > 114° (S2) may be a part of axisymmetric rings since they are found to have constant radii. After removing these points, we have 27 (S1) and 56 (S2) points as representing samples of non-axisymmetric spirals, with the opening angle of \( \sim 15^\circ \) for both S1 and S2. We estimate that the uncertainty of the location of the maxima is given by the FWHM of the PSF.
In order to fit the non-axisymmetric structures by Equation (1), we fix $\alpha$ and $\beta$ at 1.5 (Kepler rotation) and 0.4, respectively, as in Lyo et al. (2011), while other parameters are varied as $(0.1 < r_c < 0.9, 0 < \theta_0 < 2\pi, 0.05 < h_c < 0.25)$. Note that different values of $\beta$ yield similar results. Since it is difficult to fit $S_1$ and $S_2$ simultaneously, they are fitted independently.

The "best-fit" parameters are $(r_c, \theta_0, h_c) = (0.39, 204^\circ, 0.08)$ for $S_1$ (reduced $\chi^2 = 0.52$) and $(r_c, \theta_0, h_c) = (0.9, 353^\circ, 0.24)$ for $S_2$ (reduced $\chi^2 = 0.31$). The spiral shapes with these parameters are shown in Figure 4. However, the parameter degeneracy is significant. Figure 5 shows the parameter space of $(r_c, \theta_0)$ with 63.8% confidence level for $h_c = 0.1$ and $h_c = 0.2$. Note that in Figure 5, the "best-fit" of $(r_c, \theta_0)$ is outside the domain of confidence in some cases because $h_c$ is not the same as the best-fit. Despite the parameter degeneracy, the values of the aspect ratio which fit the shape of the spiral ($h_c \sim 0.1$) are consistent with those obtained from the sub-mm map of the disk (e.g., $h = 0.096(r/100\text{AU})^{0.15}$; Andrews et al. 2011).

The spiral density wave theory predicts that the pattern speed deviates from the local Kepler speed;

$$\Omega_{\text{pattern}} = 0.8 \left( \frac{r_c}{70\text{AU}} \right)^{-3/2} \left( \frac{M_c}{1.7M_\odot} \right)^{1/2} \text{[deg/vr]}$$

\[ \text{(2)} \]
Spiral in the Disk of SAO 206462

**FIG. 5.** Parameter degeneracy of the fitting for S1 (top) and S2 (bottom) with $h_c = 0.1$ (left) and $h_c = 0.2$ (right). The red points show a part of the data fitted. The green curves indicate the 68.8% confidence level for the locations of $(r_c, \theta_0)$. The magenta crosses are $(r_c, \theta_0)$ for the best-fit parameters. Note that the best-fit values of $h_c$ are different from those shown in the figure.

is not necessarily equal to $\Omega(r)$. When $r_c = 0''/5(\sim 70\text{AU})$, the spiral will move $\sim 10^\circ$ in a decade, corresponding to movement of 0.1. Considering the PSF scale of our observations and the locations of the spirals, such deviations can be detectable over a couple of decades. Moreover, if the two spirals have distinct corotation radii, their relative locations change in time due to the pattern speed difference. Such measurements will confirm that the observed feature is really the density wave, providing indisputable evidence of dynamical activity.

Note that it would be difficult to detect spirals in colder disks (smaller $h_c$), where spirals are more tightly wound, due to the blurring by the PSF. The lower detectable limit of $h_c$ is typically $h_c \sim 0.01 - 0.03$ for our set of parameters. The combination of high angular resolution and warm temperatures allows the spiral structure in the SAO 206462 disk to be resolved. Further spirals might be detectable in similarly warm disks.

### 5. SUMMARY AND DISCUSSION

In this Letter, we present a high-resolution image of the SAO 206462 transitional disk using Subaru/HiCIAO, with an inner working angle of 0''/2. We discover non-axisymmetric spiral features, which can be explained by the spiral density wave theory with a reasonable value of the disk aspect ratio ($h_c \sim 0.1$). The model is robust in a sense that it does not assume the origin of such structure explicitly.

The detection of scattered light within the sub-mm cavity itself is interesting, since Andrews et al. (2011) predicts
that the sub-mm cavity is heavily depleted. Our data in tandem with the millimeter data may suggest that the depletion of grains at different sizes is not uniform. Dong et al. (2012) discuss such discrepancies between sub-mm dust continuum images and NIR scattered light images in terms of differing spatial distributions as a function of grain size from a general theoretical perspective.

Our major assumption is that \( P = H \)-band, tracing the scattered light at the disk surface, actually traces the surface density variations. This assumption is valid when the disk is in vertical, isothermal hydrostatic equilibrium without rapid radial surface density variations (e.g., Muto 2011). Structures near the midplane are, however, preferentially observed at longer wavelengths with high spatial resolution: Atacama Large Millimeter/Submillimeter Array (ALMA) can be an ideal instrument.

Among several possible causes for the spiral structures (see also Hashimoto et al. 2011), one interesting idea is that planets excite them. In this case, the domain of possible locations of the planets is given by the green curves in Figure 5. If the two spirals have distinct corotation radii, there may be two (unseen) planets embedded in the disk. The amplitude of the surface density perturbation scales with the planet mass as \( \delta \Sigma / \Sigma \sim GM_p \Omega / c_s^2 \) for non-gap-opening low-mass planets \( (G M_p c_s^2 \ll 1\) e.g., Tanaka et al. 2002). In our data, the amplitude of the spiral wave is typically \( \sim 30\% \) (Figure 2), implying \( M_p \sim 0.5 \) \( M_J \).

The typical error of \( P \) in our image is \( \sim 5\% \). If this is typical of HiCIAO, it is capable of detecting the indirect signatures of planets down to \( M_p \sim 0.05 \) \( M_J \), ADI is promising in finding a point source; however, small field rotation (\( \sim 13^\circ \)) due to the southerly declination (\(-39^\circ\)) of SAO 206462 makes obtaining the total intensity difficult in our data. Future \( E \)-band observations may reveal thermal emission from a planet, if it exists, or its surrounding (accreting) gas.

The authors thank Roman Rafikov for comments, the support staff members of the IRTF and REM telescopes for assistance in obtaining the SED data, and the IR&D program at The Aerospace Corporation. REM data in this study were obtained under Chilean National TAC programs CN2011A-050 and CN2011B-31.
