ABSTRACT

**Context.** HD 172555 is a young A7 star belonging to the \( \beta \) Pictoris Moving Group that harbours a debris disc. The *Spitzer* IRS spectrum of the source showed mid-IR features such as silicates and glassy silica species, indicating the presence of a warm dust component with small grains, which places HD 172555 among the small group of debris discs with such properties. The IRS spectrum also shows a possible emission of SiO gas.

**Aims.** We aim to study the dust distribution in the circumstellar disc of HD 172555 and to assess the presence of gas in the debris disc.

**Methods.** As part of the GASPS Open Time Key Programme, we obtained *Herschel*-PACS photometric and spectroscopic observations of the source. We analysed PACS observations of HD 172555 and modelled the Spectral Energy Distribution (SED) with a modified blackbody and the gas emission with a two-level population model with no collisional de-excitation.

**Results.** We report for the first time the detection of [OI] atomic gas emission at 63.18 \( \mu \text{m} \) in the HD 172555 circumstellar disc. We detect excesses due to circumstellar dust toward HD 172555 in the three photometric bands of PACS (70, 100, and 160 \( \mu \text{m} \)). We derive a large dust particle mass of \((4.8 \pm 0.6) \times 10^{30} \, M_\oplus\) and an atomic oxygen mass of \(2.5 \times 10^{-2} R^2 \, M_\odot\), where \(R \) in AU is the separation between the star and the inner disc. Thus, most of the detected mass of the disc is in the gaseous phase.

**Key words.** Stars: individual: HD 172555 – Line: formation – Kuiper belt: general – Stars: pre-main sequence – Circumstellar matter

1. Introduction

Circumstellar discs play a key role in understanding how planets form and evolve, since it is thought that they originate in gas-rich circumstellar discs around young stars, the so-called protoplanetary discs. Around older stars, with ages greater than about 5 to 10 Myr, another type of disc is seen: dusty, optically thin debris discs that are produced by destructive collisions between planetesimals formed in the protoplanetary disc phase. The younger debris discs (~ 5 – 100 Myr) are the likely sites of ongoing terrestrial planet formation, while the older ones (0.1 – 1 Gyr) correspond to the “clearing out” phase, when most planetesimals left over from planet formation are removed from the system.

While debris dust has been extensively observed, previous studies have provided little unambiguous information on the chemical composition of the dust. Most debris discs have featureless IR spectra, since the grains are large and cold. However, there are a few debris discs that show strong solid-state mid-IR spectral features, indicating the presence of small, warm grains. These debris discs are probably highly transient and are produced during periods of intense collisional grinding between large bodies (Lisse et al. 2008, 2009). Gas can provide additional compositional information, but it is rarely detected in debris discs. Only two – 49 Ceti and HD 21997 – show any trace of sub-mm CO emission, indicating that typical debris gas abundances are low relative to those in younger protoplanetary discs (Dent et al. 2005, Moór et al. 2011). The only debris disc with a fairly complete inventory of its gaseous species is \( \beta \) Pictoris, primarily obtained through UV/optical absorption spectroscopy (Roberge et al. 2006). In general, the debris gas studied so far appears to be primarily low density and ionized, because these low-density discs are optically thin to dissociating UV photons.

HD 172555 (Gray et al. 2006) is one of these rare stars with an observed warm debris disc. This A7V-type star located at 29.2 pc (Gray et al. 2006) belongs to the \( \beta \) Pictoris Moving Group (BPMG), and as such, its age is in the range 12 Myr (Zuckerman & Song 2004) to 20 Myr (Barrado y Navascués et al. 1999). HD 172555 was originally found to harbour a bright debris disc through IRAS measurements of excess thermal emission attributed to circumstellar dust grains (Cote 1987). The *Spitzer*-IRS spectrum revealed strong solid-state emission features in the mid-IR, indicating that it contains a relatively large amount of warm dust in a fine \( \mu \text{m} \)-sized population at \( T \sim 300 \, \text{K} \) (Lisse et al. 2009). It has been proposed that this disc is the aftermath of a catastrophic collision between planetary mass bodies.

In this paper, we present *Herschel* (Pilbratt et al. 2010) far-IR photometry and spectroscopy of HD 172555, obtained as part of the “Gas in Protoplanetary Systems” (GASPS) *Herschel* Open Time Key Programme with the instrument PACS (Poglitsch et al. 2010). In Sec. 2 we describe the PACS spectroscopic and photometric observations. In Sec. 3 we describe the main observational and modelling results for the dust and gas discs. In Sec. 4, we discuss possible origins for the detected OI gas.
Fig. 1. HD 172555 SED. The dashed line represents the photospheric contribution fitted using VOSA (Bayo et al. 2008) with $T_{\text{eff}} = 7800$ K, $\log g = 4.5$, $L_{\text{star}}/L_{\odot} = 7.8$, while the solid one represents a photosphere plus modified blackbody model with $T = 280$ K and $\beta = 0.2$. Blue dots represent Herschel-PACS photometric points.

### 2. Observations and data reduction

#### 2.1. Herschel photometry

HD 172555 falls into the field of view of our scan maps (obsids: 1342209059, 1342209060, 1342209061, 1342209062) centred on CD-64 1208, an M0-type star with which it forms a wide binary system on a ~ 2000 AU orbit (Feigelson et al. 2006). Photometry was acquired with standard minimap configuration, with a scan length of 3′ and scan angles 70° and 110° for the 70 and 100 μm bands. The Herschel-PACS photometer observes simultaneously in 70/100 μm and 160μm, so this gave us four maps at 160 μm. Photometric observations were reduced using HIPE 8. We combined the final images at the same wavelength using IRAF (http://iraf.noao.edu) IMCOMBINE, weighting the images with the exposure time. We performed aperture photometry with an aperture radius of 6″ for the 70 and 100 μm bands and 12″ for the 160 μm band. Photometric errors were computed by averaging the standard deviation in nine positions surrounding the source scaled with the square root of the number of pixels inside the aperture. Finally, we applied the aperture corrections supplied by the PACS team. Photometric fluxes are listed in Table 1. The source is point-like in the three PACS bands. The PACS photometric points are shown in blue in Fig. 1.

#### 2.2. Herschel spectroscopy

The star was observed in chop/nod line spectroscopic mode with PACS on March 8, 2011 and September 10, 2011. PACS allows imaging of a 47″ × 47″ field of view, resolved into 5 × 5 pixels

### 3. Results

#### 3.1. Star properties and evolutionary status

A compilation of data from the literature was made to model the Spectral Energy Distribution (SED, see Table B.1). We also retrieved IRAC observations from the Spitzer Space Telescope archive (AOR 3923456 for 3.4, 4.5 and 5.0 μm bands and 2520432 for the 8.0 μm) and extracted aperture photometry using MOPEX. The IRAC 3.6 and 4.5 μm photometry is saturated. The stellar parameters were computed by fitting Johnson, Strömgren, and 2MASS photometry with Kurucz photospheric models making use of the Virtual Observatory SED Analyzer (VOSA, Bayo et al. 2008). We find a value of $7.8 \pm 0.7 L_\odot$ for the stellar luminosity (while Wyatt et al. 2007, finds $9.5 L_\odot$), and $7800 \pm 200$ K for the effective temperature, while Chen et al. (2006) finds $T_{\text{eff}} = 8550$ K, and Wyatt et al. (2007); Lisse et al. (2009) used $T_{\text{eff}} = 8000$ K.

Fig. 3 shows the position of the star in the Hertzsprung-Russell (HR) diagram. An error of ±200 K was adopted for $T_{\text{eff}}$ and the error bar in the luminosity corresponds to the uncertainty of 0.2 pc. The evolutionary tracks and isochrones from the Yonsei-Yale group (Yi et al. 2001) were used. Since the metallicity of this object is almost solar ([M/H]=0.09, Gray et al. (2006)) the set with $Z=0.02$ (solar) was chosen. According to this comparison, we find $M_* = 1.68 M_\odot$, and $\log g_*=4.28$, which implies $R_* = 1.56 R_\odot$. Given the position of the star and the uncertainties, we can only set a lower limit to the age of ~ 17 Myr (Fig. 3). The different ages quoted for BPMG members range from 12 to 50 Myr, although the latter is an upper limit.
produce the entire dust population that produces the mid-IR excess can also produce a poor fit to the SED. Rebull et al. (2008) fitted a simple blackbody fit gives a higher temperature of 329 K, with an opacity index (for λ > λ9 K, with an opacity index (for Rayleigh–Jeans regime and α = 0.1–0.5 AU). The infrared excess computed by integrating the model is 86 times higher than the maximum value expected from steady-state collisional evolution under their modelling assumptions at an age of 12 Myr. Although a different parameter selection could perhaps explain the departure from the maximum value, the authors pointed out that a major stochastic event may be playing a role.

Emission features in the Spitzer/IRS spectrum of HD 172555 were modelled by Lisse et al. (2009), who suggested the presence of glassy silica. They also tentatively attributed faint features to rovibrational transitions of SiO gas. They concluded that the dust composition, and the presence of SiO gas (if confirmed), point to a violent production process, such as an hypervelocity collision between massive planetary bodies. This suggestion was additionally supported by the hypervelocity collision experiments conducted by Takasawa et al. (2011). These authors found that the ejecta typically had a steeper grain size distribution than expected for an equilibrium distribution in a standard collisional cascade, as proposed by Lisse et al. (2009).
describe the warm dust in HD 172555 (\(dn/da \sim a^{-3}\)). This would argue for a source of fresh material, which would have had to be produced within the last 0.1 Myr to be consistent with SiO recondensation. Recently, Palhevan et al. (2011) showed that silicate constituents (Si, Fe, Mg and O) can be produced in the form of gas during hypervelocity collisions. Therefore, one can speculate that the origin of atomic oxygen detected with Herschel could be the violent event proposed by Lisse et al. (2009) to explain the shape of the Spitzer-IRS spectrum.

4.2. Gas accumulation over time

The extremely low sensitivity of OI to the radiation pressure from this A-type star (Fernández & Wyatt 2006) opens the door to alternative, perhaps less catastrophic scenarios as for the origin of the detected OI gas. Atomic oxygen could indeed accumulate over time at the place where it is produced. For instance, the considerable collisional activity in the dust ring presumably releases a population of poorly bound, or unbound grains due to radiation pressure, which can collisionally vaporize larger grains due to high relative velocities. This has been proposed by Czechowski & Mann (2007) to explain the stable gas in the co-evol β Pictoris system. Assuming that oxygen is originally locked into olivine grains, a dust mass of \(\sim 0.9 M_\odot\) would need to have been vaporized in less than 12 Myr, corresponding to a mass rate higher than \(7 \times 10^{-8} M_\odot/yr (10^{15} g/s)\). Interestingly, this value compares to the mass rate derived by Czechowski & Mann (2007) at the peak position of the β Pictoris dust disc (50–100 AU).

The sublimation of grains close to the star, at \(\sim 0.1–0.5\) AU, could also contribute to the production of OI. Although the 4 AU-radius dust ring is collision-dominated, models by Wyatt (2005) and Löhne et al. (2012) show that, even in this case, a fraction of the dust grains can escape the collisional cascade and migrate toward the star by Poynting-Robertson (P-R) drag. Silicates extracted from the ring will eventually reach sufficiently high temperatures as they approach the star and produce O, SiO and MgO, and ultimately Si, Mg and O. Assuming again that O is locked in olivine grains, a reference dust mass of \(\sim 10^{-3} M_\odot\) would need to have been extracted from the dust belt by P-R drag to explain the PACS data over an unknown time span. A strict minimum supplying mass rate of about \(10^{-10} M_\odot/yr\) is obtained assuming a unit efficiency in atomic O production by sublimation over the longest possible time span (12 Myr), and assuming that the gas has not viscously flown inward or outward. On the other hand, the P-R drag timescale for bound grains in the 4-AU radius dust ring, \(t_{P-R} > 7500\) yr (e.g. Wyatt 2005), yields an upper limit on the present-day P-R drag mass loss rate of a few \(10^{-7} M_\odot/yr\). This implies that this process had to last for longer than a few 10^9 yr.

4.3. Discussion

Different scenarios can qualitatively explain the OI enrichment of the HD 172555 disc. We note that these are not necessarily mutually exclusive since gas accumulation could follow the giant collision proposed by Lisse et al. (2009), if it did not occur too recently. For instance, it takes about 1 Myr for the debris created in a giant impact to form an axisymmetric disc (Jackson & Wyatt 2012), and be consistent with observational constraints (Smith et al. 2012). This may leave sufficient time to accumulate OI gas at some place in the disc. Additional processes, such as comet evaporation or grain photodesorption (Chen et al. 2007), also deserve to be mentioned as possible OI providers. In summary, the origin of the detected OI gas remains open, and detailed modelling of the processes discussed here, as well as the detection of atomic or ionized Fe, Mg, and Si will help to identify the source of OI gas.

5. Summary and conclusion

Our main results can be summarized as follows:

1. We report the detection of the [OI] line in the debris disc of HD 172555 with a flux of \((9.2 \pm 2.4) \times 10^{-18}\) W/m². This is the first unambiguous detection of gas in this system.

2. We modelled the SED of the object with a Kurucz photospheric model (\(T_{eff} = 7800\) K, \(log g = 4.5\), \(L_{star} = 7.8 L_\odot\)) plus a modified blackbody to fit the infrared excess at \(A > 7\) μm. We obtain \(T_{dust} = 280\) K and \(\beta = 0.2\). We derive a dust mass of \(\sim 4.8 \times 10^{-4} M_\odot\).

3. Using purely analytical relations and simple assumptions, we derive an [OI] mass of \(2.5 \times 10^{-5} R^2 M_\odot\) where \(R\) is the unconstrained radial location of the gas.

4. Although the spatial origin of the line is uncertain, we speculate about a possible origin in an hypervelocity collision, or in gas accumulation over time due to the low radiation pressure on atomic oxygen.

5. HD 172555 provides a valuable window on the processes that occur during the early stages of terrestrial planet formation, including massive collisions like the one that produced Earth’s moon (Canup & Esposito 1996).

Appendix B: How to derive the oxygen mass

In the following we explain how to derive the atomic oxygen gas mass from prompt emission level population. To estimate the mass of oxygen gas we consider the excitation of atomic oxygen to its first fine structure level in the absence of a collisional partner. This situation happens in very low density environments such as debris discs. The main mechanism involved is the so-called prompt emission and fluorescence. The prompt emission involves the absorption of a photon from the star or from the dust at the precise wavelength of the atomic emission, and subsequent re-emission. To model the emission, we assume that the ground state is the most populated. The population at steady-state for level $^1P_2$ is given by:

$$0 = -n_1(A_{10} + B_{10}J_{10}) + n_0B_{01}J_{10}.$$  

(B.1)

Assuming that only the first two levels are populated ($n = n_0 + n_1$),

$$x = \frac{n_1}{n} = \frac{1}{1 + B_{10}/A_{10} + A_{10}/B_{01}J_{10}}.$$  

(B.2)

since $g_1B_{10} = g_1B_{01}$ and $B_{10} = (c^2/2\hbar^2)\lambda_{10}$, the fractional population is

$$x = \frac{n_1}{n} = \frac{1}{1 + g_1B_{01}/g_1B_{10}(2\hbar^2/c^2\lambda_{10}).}$$  

(B.3)

For $O_1$ we have $g_0 = g_1 = 3$. $J_{10}$ is computed using the distance-diluted stellar flux in the Rayleigh-Jeans regime at 63 μm:

$$J_{10} = \frac{1}{4\pi} \left[ \frac{R}{r} \right]^2 \frac{2\pi kT}{\lambda^2}.$$  

(B.4)

where $R$ is the distance to the star and $r$ the stellar radius. We obtain $J_{10} = 2.273 \times 10^{-15} (1AU/R\text{AU})^2$ erg s$^{-1}$ cm$^{-2}$ Hz$^{-1}$ sr$^{-1}$, and the fractional population is thus: $x = 8.67 \times 10^{-5}$.

The number of oxygen atoms given the flux in cgs is then

$$N_{[O_1]} = 9.5216 \times 10^{18} \frac{F_{[O_1]}(\lambda_{10}^{-1}\text{cm}^{-2}\text{s}^{-1})}{A_d} \text{AU}.$$  

(B.5)

where $9.5216 \times 10^{15}$ combines the conversion from arcsec$^2$ to steradian and from AU to parsec.

The effect of including additional excitation paths is negligible. We compare this with a situation when the emission is produced at 1 AU from the star. For example, if we include all main fluorescence pumping paths ($^2P_3 \rightarrow ^1S_0 \rightarrow ^1P_1$, $^2P_1 \rightarrow ^1D_2 \rightarrow ^1P_1$, and $^2P_1 \rightarrow ^1S_0 \rightarrow ^1D_2 \rightarrow ^1P_1$), the final mass of oxygen is $M([O_1]) = 0.0247$ M$_\odot$, compared to $M([O_1]) = 0.025$ M$_\odot$ obtained when we only include the main excitation path.

Notes. (1): Johnson et al. (1966); (2): 2MASS catalogue (Skrutskie et al. 2006); (3): Tycho-2 catalogue (Hog et al. 2000); (4): IRAS faint source catalogue; (5): Rebull et al. (2008); (6): Hauck & Mermilliod (1998); (7): present work; (8): Moerchen et al. (2010); (9): Nilsson et al. (2009), see text; (10): Ishihara et al. (2010); (11): WISE Preliminary Release Source Catalog. The WISE magnitude limits in the Explanatory Supplement indicate that the 3.4, 4.6 and 12 μm photometry of HD 172555 is saturated. However, the WISE pipeline performs PSF fitting when dealing with saturated sources and produces accurate results for bands 1, 3, and 4. Unfortunately, for band 2 at 4.6 μm the pipeline does not produce good results for saturated sources (K. Stapelfeldt, private communication); (12): Schütz et al. (2005); (13): photometry reduced by us with MOPEX from IRAC archive data. IRAC1, IRAC2 and IRAC3 measurements are saturated.
