Since its founding, NASA has been dedicated to the advancement of aeronautics and space science. The NASA Scientific and Technical Information (STI) program plays a key part in helping NASA maintain this important role.

The NASA STI Program operates under the auspices of the Agency Chief Information Officer. It collects, organizes, provides for archiving, and disseminates NASA's STI. The NASA STI program provides access to the NASA Aeronautics and Space Database and its public interface, the NASA Technical Reports Server, thus providing one of the largest collections of aeronautical and space science STI in the world. Results are published in both non-NASA channels and by NASA in the NASA STI Report Series, which includes the following report types:

- **TECHNICAL PUBLICATION.** Reports of completed research or a major significant phase of research that present the results of NASA programs and include extensive data or theoretical analysis. Includes compilations of significant scientific and technical data and information deemed to be of continuing reference value. NASA counterpart of peer-reviewed formal professional papers but has less stringent limitations on manuscript length and extent of graphic presentations.

- **TECHNICAL MEMORANDUM.** Scientific and technical findings that are preliminary or of specialized interest, e.g., quick release reports, working papers, and bibliographies that contain minimal annotation. Does not contain extensive analysis.

- **CONTRACTOR REPORT.** Scientific and technical findings by NASA-sponsored contractors and grantees.

- **CONFERENCE PUBLICATION.** Collected papers from scientific and technical conferences, symposia, seminars, or other meetings sponsored or cosponsored by NASA.

- **SPECIAL PUBLICATION.** Scientific, technical, or historical information from NASA programs, projects, and missions, often concerned with subjects having substantial public interest.

- **TECHNICAL TRANSLATION.** English-language translations of foreign scientific and technical material pertinent to NASA's mission.

Specialized services also include creating custom thesauri, building customized databases, organizing and publishing research results.

For more information about the NASA STI program, see the following:

- Access the NASA STI program home page at [http://www.sti.nasa.gov](http://www.sti.nasa.gov)
- E-mail your question to help@sti.nasa.gov
- Fax your question to the NASA STI Information Desk at 443–757–5803
- Phone the NASA STI Information Desk at 443–757–5802

Abstract

The results of an experimental calibration of the NASA Glenn Research Center 16 in. Mass-Flow Plug (MFP) are presented and compared to a previously obtained calibration of a 15 in. Mass-Flow Plug. An ASME low-beta, long-radius nozzle was used as the calibration reference. The discharge coefficient for the ASME nozzle was obtained by numerically simulating the flow through the nozzle from the WIND-US code. The results showed agreement between the 15 and 16 in. MFPs for area ratios (MFP to pipe area ratio) greater than 0.6 but deviate at area ratios below this value for reasons that are not fully understood. A general uncertainty analysis was also performed and indicates that large uncertainties in the calibration are present for low MFP area ratios.

Introduction

Large-scale model supersonic aircraft inlets are routinely tested in NASA Glenn Research Center’s (GRC) larger wind tunnels such as the 8- by 6-ft and 10- by 10-ft Supersonic Wind Tunnels (SWT). Two key objectives of such tests are to ensure that the air supplied by an inlet matches the mass-flow demand of an engine and that the inlet operates in a stable condition over a wide range of mass-flows. Thus, accurate measurement of inlet mass-flow is of primary importance. Due to its relatively simple mechanical design, the mass flow through an inlet is often controlled and measured by a calibrated conical mass-flow plug (MFP). For larger models, GRC uses a 16 in. diameter MFP which was fabricated by modifying a pre-existing 15 in. MFP. Calibration of the 16 in. MFP plug was performed in-house using an ASME low-beta, long-radius nozzle as the reference measurement. The procedure and resulting calibration, as well as a comparison to the calibration of the previous 15 in. MFP are reported herein.

Calibration Procedure

The calibration of both the caged 15 and 16 in. mass-flow plugs were carried out with the experimental setup shown in Figure 1. The four primary components of the calibration rig are the American Society of Mechanical Engineers (ASME) inlet flow nozzle assembly, an adapter spool piece, the cold-pipe assembly, and the mass-flow plug assembly. The entire calibration assembly was mounted vertically on the floor of GRC’s 10- by 10-ft Supersonic Wind Tunnel and protruded through a sealed opening in the ceiling. The ASME nozzle was fed by atmospheric ambient pressure and temperature air while the wind tunnel exhausters were used as a vacuum source to establish a flow through the assembly. A photo of the ASME nozzle on the top of the 10- by 10-ft. SWT is shown in Figure 2 and a schematic of the geometry is shown in Figure 3. A photo of the 16 in. MFP attached to the cold-pipe is shown in Figure 4 and a schematic of the plug is shown in Figure 5.

The spool piece is an adapter to match the ASME nozzle exit diameter to the cold-pipe diameter under test. The cold-pipe is simply a 96 in. long constant-area pipe whose primary purpose is to allow for a flow-settling length between the inlet exit and the mass-flow plug. Near the forward end is a spherical-nosed centerbody supported by three equally spaced struts. The centerbody nose is intended to simulate the fan spinner on a turbojet engine. Attached to the forward end of the cold-pipe is a spool piece that houses eight compressor face rakes. The rakes lie in the plane of the tip of the centerbody nose. The inside edge at the exit plane of the cold-pipe is sharp to fix the position of the mass-flow plug choke point.
A picture of the 16-in. mass-flow plug attached to the cold-pipe is shown in Figure 4. The cone is actuated by a hydraulic cylinder and concentricity of the cone with the cold-pipe is maintained by wedge bearings on three of the six knife-edged support struts (cage). A position transducer (potentiometer) can be seen on the top of the assembly in Figure 4.

The ultimate goal of the calibration is to determine the discharge coefficient for the 16 in. MFP over an operating range typical of the supersonic inlet testing. The discharge coefficient for the mass-flow plug is defined as:

$$C_{D,\text{plug}} = \frac{w_{\text{noz}}}{w_{\text{plug},i}}$$  (1)

where $w_{\text{noz}}$ is the actual mass flow through the cold-pipe and $w_{\text{plug},i}$ is the ideal inviscid choked flow through the mass-flow plug. For the purpose of calibrating the mass-flow plug, the actual mass flow was measured with an ASME Long-Radius Flow Nozzle. A description of this nozzle is as follows.

**ASME Nozzle**

**Geometry:** An ASME Long-Radius Flow Nozzle with throat taps was used to provide a reference mass-flow measure for calibrating both the 15 and 16 in. mass-flow plugs. The geometry of the nozzle is shown in Figure 3. This design conforms to the Low-β Nozzle with Throat Taps illustrated in Fig. II-III-14 of Reference 2 with the following two exceptions. First, no approach pipe exists before the nozzle $(D=\infty)$, hence $\beta=d/D=0$. And second, the nozzle exit flow does not exhaust into a sudden expansion but rather into a shallow angle conical diffuser. The nozzle throat-to-conical diffuser and conical diffuser-to-constant area end section are both transitioned by 27.96 in. radii.\(^1\)

\(^1\) Note that this diffuser geometry differs from the description given by Iek (Ref. 1) where the diffuser is described as being a “cubic contour.”
Citing the desire to maintain fully turbulent flow in the nozzle, the calibration tests were performed both with and without a boundary-layer trip in the inlet region of the nozzle. Details of the trip were not supplied by Iek (Ref. 1) but inspection of the ASME nozzle indicated the trip location and width are as shown in Figure 3. Most of the tests were performed with an 80 grit trip, but limited testing was also performed with a 36 grit trip with essentially the same results.

**Flow Equations:** The flow through the ASME nozzle is calculated by the following equation:

\[ w_{\text{noz}} = C_{D,\text{noz}} \cdot w_{\text{noz},i} \]  

(2)

where

\[ w_{\text{noz},i} = \rho_{\text{noz}} \cdot U_{\text{noz}} \cdot A_{\text{noz}} \]  

(3)

and where \( \rho_{\text{noz}} \) and \( U_{\text{noz}} \) are evaluated at the throat of the ASME nozzle. Substitution of the ideal gas law, Mach number definition, and isentropic and adiabatic relations for pressure and temperature, respectively:

\[ \rho_{\text{noz}} = \frac{144 \cdot p_{\text{noz}}}{R_{\text{air}} \cdot T_{\text{noz}}} \]  

(4)

\[ U_{\text{noz}} = M_{\text{noz}} \cdot \sqrt{\gamma \cdot g_c \cdot R_{\text{air}} \cdot T_{\text{noz}}} \]  

(5)

\[ p_{\text{noz}} = \frac{p_{\text{t,\text{noz}}}}{\left(1 + \frac{\gamma - 1}{2} \cdot M_{\text{noz}}^2\right)^\frac{\gamma - 1}{\gamma \cdot (\gamma + 1)}} \]  

(6)

\[ T_{\text{noz}} = \frac{T_{\text{t,\text{noz}}}}{1 + \frac{\gamma - 1}{2} \cdot M_{\text{noz}}^2} \]  

(7)

into the expression for \( w_0 \) and rearranging yields:

\[ w_{\text{noz},i} = \sqrt{\frac{\gamma \cdot g_c}{R_{\text{air}}} \cdot \frac{p_{\text{t,\text{noz}}} \cdot M_{\text{noz}} \cdot A_{\text{noz}}}{\sqrt{T_{\text{t,\text{noz}}}}} \cdot \left(1 + \frac{\gamma - 1}{2} \cdot M_{\text{noz}}^2\right)^\frac{\gamma - 1}{2(\gamma - 1)}} \]  

(8)

Substituting the values for \( \gamma, g_c, \) and \( R_{\text{air}} \) and replacing \( p_{\text{t,\text{noz}}} \) and \( T_{\text{t,\text{noz}}} \) with \( p_{\text{amb}} \) and \( T_{\text{amb}} \), respectively, gives the final form:

\[ w_{\text{noz},i} = 0.91884 \cdot \sqrt{\frac{p_{\text{amb}}}{{\text{M}_{\text{noz}}} \cdot A_{\text{noz}}} \cdot \left(1 + 0.2 \cdot M_{\text{noz}}^2\right)^{-3}} \cdot \sqrt{T_{\text{amb}}} \]  

(9)

where \( M_{\text{noz}} \) is the Mach number of the flow at the throat of the nozzle and is given by the isentropic relation:

\[ M_{\text{noz}} = \sqrt{5 \cdot \left(\frac{p_{\text{amb}}}{p_{\text{noz}}} \cdot \left(\frac{1}{3.5}\right)\right) - 1} \]  

(10)

and \( p_{\text{noz}} \) is the static pressure measured at the throat of the nozzle. All of the variables in Equations (9) and (10) are directly measured or calculated from directly measured quantities. The only remaining parameter required to calculate the nozzle flow rate is the nozzle discharge coefficient \( (C_{D,\text{noz}})\).
ASME Nozzle Discharge Coefficient

**Historical Correlation:** The discharge coefficient for a nozzle with throat taps is a function of the potential flow non-uniformity and the boundary-layer displacement thickness resulting from viscous effects. As discussed by Rivas and Shapiro (Ref. 3), if the length of the cylindrical sections before and after the throat taps are on the order of or greater than ¼ throat diameter, then the effects of potential flow non-uniformity are negligibly small.

In the absence of a calibration, ASME recommends reading the discharge coefficient for a low-β long-radius nozzle with throat taps from Fig. II-III-19 of Reference 2. The source of this curve is not referenced but it appears to be the “Calculated Curve” in Fig. 22 of Cotton and Westcott (Ref. 4). No uncertainty is given for using this curve but based on similar analysis, it is likely to be on the order of ±1.5 to 2.0 percent. Much of the data used to generate this curve was based on incompressible flow data. In 1973, Smith and Matz (Ref. 5) investigated an 8-in. low-β, long-radius nozzle under incompressible and compressible conditions and reported a Mach number dependence.

**Two-Code Computational Approach:** For the March 1996 calibration of the 15 in. caged mass-flow plug (Ref. 1), due to the uncertain effect of the β parameter and the nozzle exit diffuser on the discharge coefficient, the ASME correlation was not used. Instead, the theoretical method first performed by Smith and Matz (Ref. 5) and later by Lahti and Hamed (Ref. 6) was used to establish a discharge coefficient. With this method, the discharge coefficient is assumed to depend on two components, an inviscid part (Cd, pot) that accounts for the radial pressure variation in the throat, and a viscous part (Cd, δ*) that accounts for the effective boundary-layer blockage. Computer programs were used to calculate each component and the discharge coefficient of the nozzle was determined from the product of the components:

\[
C_{D,\text{noz},2C} = C_{D,\text{pot}} \cdot C_{D,\delta^*}
\]  

(11)

This approach will hereafter be referred to as the “Two-Code” (2C) nozzle calibration. In Lahti and Hamed’s (Ref. 6) study, the potential solution was obtained with the Stream Tube Curvature (STC) computer code (Ref. 7), chosen because of their many years of experience with it and because it is driven by global mass conservation as part of its solution procedure making it a natural choice for mass-flow calibration studies. The boundary-layer correction was obtained using Harris and Blanchard’s code (Refs. 8 and 9). This code was chosen based on its wide use and thorough documentation. Lahti and Hamed (Ref. 6) report that comparisons with experimentally determined discharge coefficients indicate that an accuracy of ±0.25 percent can be achieved with their method.

For the calibration of the GRC ASME nozzle, Iek (Ref. 1) followed a similar approach but used different computer codes. For the potential solution, Stockman and Farrell’s code (Ref. 10) was used and for the viscous solution, Herring’s PL2 code (Ref. 11) was used. With these codes, the theoretical discharge coefficient for the ASME nozzle was determined at six discrete throat Reynolds numbers.

For data reduction during the mass-flow plug calibrations, the data in Table 1 were interpolated with a third-order polynomial function:

\[
C_{D,\text{noz},2C} = 0.982982 + 0.002081573 \text{Re}_d - 0.0004063900 \text{Re}_d^2 + 0.00004062582 \text{Re}_d^3
\]  

(12)

and extrapolated by setting points outside the calibration range to the end points of the calibration.

**RANS Computational Approach:** More recently, a different computational approach was taken for obtaining the discharge coefficient of the ASME nozzle as well as the 16 in. MFP. Rather than use a potential code coupled with a boundary-layer calculation, WIND-US, which is a general purpose 3-D Reynolds-averaged Navier-Stokes (RANS) code, was used for the numerical studies (Ref. 12). Versions 3 Alpha and 2 of WIND-US calculated the CFD derived discharge coefficients. WIND-US is a mature, multi-zone, structured-grid, compressible flow solver offering a variety of turbulence models. All simulations were run steady-state using the Menter Shear Stress Transport (SST) turbulence model (Ref. 13). The SST turbulence model was chosen for all of the simulations because previous studies (Refs. 14 and 15) have shown that this particular model performs well for jet flows.

An axisymmetric structured grid, composed of roughly 119,000 grid points and divided into 17 zones, was used to model the test rig assembly shown in Figure 1. Grids were created for 19 different plug positions, ranging from \(x_{\text{plug}} = 2.4\) to 16.4 in. with \(x_{\text{plug}}\) defined as shown in Figure 5. Zones upstream of the experimental boundary-layer trip location (see Figure 3) assumed laminar flow while zones downstream of the...
trip location assumed turbulent flow. An example grid is shown in Figure 6 while Figure 7 illustrates the solid computer model.

The simulations used a constant Courant-Friedrichs-Lewy (CFL) number of 0.5 rather than a constant time step. To reduce computational costs and convergence time, parallel processing along with three levels of grid sequencing were used to obtain converged solutions. First, a coarse grid sequence included only every fourth point in each direction. Second, a medium grid sequence was used that utilized every other point in each direction. Third, a fine sequence used every grid point. Solution convergence was achieved when the computational equation residuals were reduced by several orders of magnitude and the mass flow rates in the bellmouth entrance and near the cold pipe exit each varied by less than 0.09 percent per iteration. Convergence was typically obtained in a little over 3 hr.

Figure 6.—Sample primary grid layout, laminar zones are in blue, turbulent zones are in red.

Figure 7.—The 90° sector of the axisymmetric solid model.
Initially, the WIND-US code was run with the as-tested ambient inlet conditions \((p_{\text{amb}}=14.3 \text{ psia})\), but then to better resolve Reynolds number effects, additional cases were run at inlet pressures of 5.0 and 50.0 psia. For all pressures, the ambient total temperature was set to 520.0 °R with an initial inflow Mach number set to 0.001. Whereas for the 5.0 psia case, the back-pressure at the MFP exit was set at 1.0 psia, for the two higher pressure cases, the back-pressure was set at the as-tested pressure of 2.0 psia.

After the CFD analyses were completed, the data was post-processed to acquire the discharge coefficients for the bellmouth nozzle. First, the mass flow rate through the cold pipe was calculated from the average mass flow rate between the downstream tangential edge of the radial nose of the conical plug to the cold pipe exit:

\[
\sum_{i=1}^{N} w_{\text{pipe},x,i} = \frac{N}{1} \tag{13}
\]

where

\[
\sum_{\theta} = \int_{\phi} \int_{r} \int_{\theta} \rho \cdot U_{x} \cdot r \cdot dr \cdot d\theta \tag{14}
\]

This was compared to the average mass flow rate at the throat of the bellmouth to check for continuity. The solution was converged when the average mass flow rates in the bellmouth throat and just upstream of the cold pipe exit varied by less than 0.09 percent of each other. The discharge coefficient could then be calculated from:

\[
C_{D,\text{noz}} = \frac{w_{\text{pipe}}}{w_{\text{noz},i}} \tag{15}
\]

where \(w_{\text{noz},i}\) is given by Equation (9).

The data from the WIND-US computations are plotted in Figure 8. For reference, the ASME curve, the data from Smith and Matz, and the numerical data from Iek are also shown. For the WIND-US data, only points where the throat Mach number was between 0.2 and 0.8 are plotted. Due to the use of a boundary-layer trip on the nozzle, the distribution does not display the transitional behavior of Smith and Matz (Ref. 5) data and indeed seems to agree well with the turbulent portion of their “Critical” curve \((Re_{D,\text{noz}} > 2.0 \times 10^6)\). Another observation of the current data is the saw-tooth nature of the combined distributions indicating a small Mach number dependence. To illustrate this dependence more clearly, data at constant Mach numbers of 0.3, 0.5, and 0.7 were extracted and are plotted in Figure 9. Although the dependence on Mach number is small for the current data, the trend is opposite that of Smith and Matz (Ref. 5), but since their low Mach number data was in the transition region, nothing firm can be drawn from this. Comparing the present WIND-US data to the previous distribution established for the same nozzle configuration by Iek (Ref. 1) shows that the present data trends about 0.2 percent higher than Iek’s.

![Figure 8.—ASME nozzle discharge coefficient.](image-url)
In order to apply easily the present data to the 16 in. MFP calibration, a correlation was developed that fits the data and accounts for the small Mach number dependence. This was accomplished by first curve fitting the $M=0.5$ data which resulted in the following expression:

$$C_{D,M=0.5} = 0.993003 - \frac{6.73896}{\sqrt{Re_d}}$$

(16)

An empirical correction to this nominal discharge coefficient was established such that the Mach number dependant discharge coefficient is defined by:

$$C_{D,oz,WU} = C_{D,M=0.5} \cdot f(M)$$

(17)

where

$$f(M) = 0.999514 \cdot \left(1 - 0.2M^2_{roz}\right)^{0.0063415}$$

(18)

Since it is unlikely that the current ASME nozzle would ever be operated at anything but ambient pressure conditions, the coefficients in Equation (18) were determined from the 14.3 psia data only. A comparison of Equation (17) and Equation (16) with the numerical data is shown in Figure 10(a) and Figure 10(b), respectively.

16 in. Mass-Flow Plug

Geometry: With reference to Figure 5, the plug itself is a $\phi = 16.5^\circ$ half-angle cone with a 2.18 in. nose radius. The downstream end of the cone is $R_{plug} = 15.800$ in. in diameter followed by a 0.610 in. wide cylindrical shoulder.

Flow Equations: The discharge coefficient for the mass-flow plug is assumed to be a function only of the plug position and defined as the ratio of the actual mass-flow to the ideal theoretical mass-flow (see Eq. (1)). The ideal mass-flow is calculated from the following equation:

$$w^*_{plug,i} = \rho_{pipe} \cdot U_{pipe} \cdot AR^{-1} \cdot A_{plug}$$

(19)

where

$$AR = \frac{A_{plug}}{A_{pipe}}$$

(20)

and where $A_{plug}$ is the choked-flow area between the cold-pipe exit plane edge and the conical plug. With reference to Figure 5, the definition of the choked area ($A_{plug}$) of the MFP is based on the area of the frustum of a right circular cone where the slant height ($s_s$) is defined as the average of the vertical distance from the cold-pipe edge to the MFP and the slant height of a cone whose slant height is normal to the MFP surface.

$$A_{plug} = \pi \cdot s_a \cdot \left(R_{pipe} + R_a \right)$$

(21)

where (see Figure 5)

$$s_n = x_{plug}' \cdot \sin(\phi)$$

$$s_v = x_{plug}' \cdot \tan(\phi)$$

$$s_a = (s_n + s_v) / 2.0$$

$$R_a = R_{pipe} - s_a \cdot \cos(\phi - \arccos(s_n / s_a))$$

(22)
and

\[ x'_{\text{plug}} = x_{\text{plug}} + \left( R_{\text{pipe}} - R_{\text{plug}} \right) / \tan(\phi) \]  

(23)

where \( x'_{\text{plug}} \) is the distance from the end of the cold-pipe to the theoretical intersection line of the plug conical surface and the cylinder of the cold-pipe internal diameter (see Figure 5). The choice of \( s_a \) to approximate the sonic line (curved line in Figure 5) is arbitrary but must be used consistently for the calibration to be valid.

The area ratio can be expressed in terms of the Mach number in the pipe by the following isentropic relation:

\[ \frac{A_{\text{plug}}}{A_{\text{pipe}}} = \left( \frac{\gamma + 1}{2} \right)^{\frac{\gamma + 1}{(\gamma - 1)(\gamma + 1)}} \cdot M_{\text{pipe}} \left( 1 + \frac{\gamma - 1}{2} \cdot M_{\text{pipe}}^2 \right)^{-\frac{(\gamma + 1)}{2(\gamma - 1)}} \]  

(24)
Substituting Equation (24) and Equations (4) to (7) (with the subscript “noz” replaced with “pipe”) into Equation (19) yields:

\[
\omega_{*\text{plug}} = \frac{\gamma - \delta_c}{R_{\text{air}}} \left( \frac{P_{\text{pipe}}}{\sqrt{T_{\text{amb}}} \cdot A_{\text{plug}}} \right) \left( \gamma + \frac{1}{2} \right)^{-\frac{\gamma+1}{2\gamma-1}}
\] (25)

The total pressure in the cold-pipe \( (P_{\text{pipe}}) \) is calculated from Equation (6) (with the subscript “noz” replaced with “pipe”). The static pressure in the cold-pipe \( (P_{\text{pipe}}) \) is directly measured with static pressure taps and the Mach number in the cold-pipe \( (M_{\text{pipe}}) \) is calculated from Equation (24) which assumes that the flow at the mass-flow plug exit is choked.

**Instrumentation:** With reference to Figure 1, the test setup was instrumented as follows. The ambient air pressure and temperature were each recorded with four transducers which were then averaged to obtain \( P_{\text{amb}} \) and \( T_{\text{amb}} \). There were a total of six throat taps on the ASME nozzle and eight static taps at the mid-point of the cold pipe. These were also averaged to obtain \( P_{\text{noz}} \) and \( P_{\text{pipe}} \). The temperatures were measured with Type-E thermocouples and the pressures were measured with ESP 8400R 0 to 15 psia modules. The data was recorded on the GRC ESCORT data acquisition system.

**Calibration Runs:** For the caged 16 in. mass-flow plug calibration runs, there were six sweeps of the mass flow plug. The first three were performed with the boundary-layer trip installed on the ASME nozzle and the last three were performed with the trip removed.

**Uncertainty Considerations**

A general uncertainty analysis was performed for both the 15 and 16 in. MFP calibrations. The uncertainty in the MFP discharge coefficients was estimated by:

\[
\delta C_{D,\text{plug}} = \sqrt{\sum_{i=1}^{J} \left( \frac{\partial C_{D,\text{plug}}}{\partial X_i} \delta X_i \right)^2}
\] (26)

where \( X_i \) are the measurands which are summarized with their assumed uncertainty in Table 2.

The measurands \( P_{\text{amb}}, P_{\text{noz}} \) and \( P_{\text{pipe}} \) are actually calculated averages of four, six and eight individual pressure measurements, respectively, and the uncertainties in Table 2 reflect the measurement redundancy. In addition, different pressure uncertainty levels were used for the 15 and 16 in. MFP calibrations to reflect an upgraded pressure measurement system for the 16 in. MFP. The measurement uncertainty for the individual modules was 0.012 and 0.009 psi for the 15 in. and 16 in. MFP, respectively (Ref. 16). The uncertainty in the nozzle discharge coefficient is comprised of two components. The first is related to the grid and solution convergence and is generally small (<0.003 percent). The second is related to how well the CFD models the flow physics. In particular, since the nozzle discharge coefficient is primarily a function of the boundary-layer growth, the turbulence model will have an influence on the result. Further, the difference between how the boundary layer transitions on the nozzle will also affect the discharge coefficient. In the CFD, the flow is assumed laminar until the leading edge of the boundary-layer trip and fully turbulent downstream. In the experiment, there is a finite width of grit material. These effects are not easily quantifiable, thus the uncertainty specified for the nozzle discharge coefficient is to be considered a “best guess” by the authors. Finally, although the ambient temperature is measured and used in the calculations, it does not contribute to the MFP discharge coefficient uncertainty.

**Results and Discussion**

**Caged 15 in. MFP Calibration**

The 15 in. MFP was calibrated over a range from \( x_{\text{plug}} = 0.25 \) to 17.0 in. with and without distortion screens installed in the cold-pipe. A correlation was established based on the data without distortion screens. The discharge coefficient was assumed to be only a function of the choked flow area ratio (Eq. (20)) and is expressed as a segmented third-order polynomial function where the coefficient values are given in Table 3:

\[
C_{D,\text{plug},2C} = c_0 + c_1 \cdot AR + c_2 \cdot AR^2 + c_3 \cdot AR^3
\] (27)

NASA/TM—2014-218128 10
This original calibration (Eq. (27)) was based on the two-code ASME nozzle calibration. To update the calibration to use the more recent WIND-US based nozzle calibration, two approaches are possible. First, the data calibration data points could be recalculated with the WIND-US based nozzle calculation and a new fit established, or second, an adjustment could be applied to Equation (27) by multiplying by the ratio of nozzle discharge coefficients:

\[ C_{D,\text{plug,WU}} = C_{D,\text{plug,2C}} \cdot \left( \frac{C_{D,\text{noz,WU}}}{C_{D,\text{noz,2C}}} \right) \quad (28) \]

The nozzle discharge coefficients based on both methods are plotted in Figure 11 as a function of the 15 in. MFP area ratio. Also plotted is the ratio of the coefficients which can be approximated by the following empirical relation:

\[
\frac{C_{D,\text{noz,WU}}}{C_{D,\text{noz,2C}}} = 1.0014446 + 0.017657109 \cdot \text{AR} \\
- 0.00069852959/\text{AR} - 0.046818586 \cdot \text{AR}^2 \\
+ 2.3567944 \times 10^{-5}/\text{AR}^2 + 0.049185331 \cdot \text{AR}^3 \\
- 4.4263225 \times 10^{-7}/\text{AR}^3 - 0.018204318 \cdot \text{AR}^4 \quad (29)
\]

The original and adjusted 15 in. MFP calibrations along with the data they were derived from are shown in Figure 12. The nozzle Mach number and Reynolds number are also plotted for reference. With regard to the original calibration, there are a couple of things to note about this distribution. At area ratios below approximately 0.2, the curve has a large negative slope and at the lowest area ratio, the discharge coefficient exceeds unity with large data scatter. At the largest area ratio, the slope and scatter also increases. During the test, the ratio of the cold-pipe base pressure to pipe total pressure is monitored to ensure the plug is operating under choked conditions. The two highest area ratio positions are approaching flow conditions that challenge the assumption of a well-defined choked flow.

The adjusted 15 in. MFP discharge coefficient curve fit is re-plotted in Figure 13 with the uncertainty bounds from the general uncertainty analysis. Also plotted is the percent uncertainty based on the assumed measurand uncertainties (Table 2).

These results indicate that the measurement uncertainty exceeds 0.5 percent for MFP area ratios below 0.5. Based on this calibration, the inlet should be sized to operate within the area ratio range 0.2<AR<0.8 (1.85 in.<x_{plug}<10.4 in.).

The relative contribution from the individual measurands is plotted in Figure 14. Also plotted for reference is the absolute uncertainty. The large uncertainty at low area ratios is primarily due to the low Mach number in the nozzle (see Figure 12) which is calculated from Equation (10).

Figure 11.—ASME Nozzle discharge coefficient as a function of 15 in. MFP area ratio.
Figure 12.—Original and adjusted 15 in. MFP discharge coefficient

Figure 13.—The 15 in. MFP discharge coefficient uncertainty.
Caged 16 in. MFP Calibration

The results of the calibration of the 16 in. MFP for both tripped and un-tripped nozzle boundary layer are shown Figure 15. The nozzle Mach number and Reynolds number are also plotted for reference. At a given area ratio, due to its larger size, the 16 in. MFP has a larger flow rate than the 15 in. MFP. At large area ratios, this results in choking of the nozzle for the 16 in. MFP. Thus data beyond an area ratio of 0.7 will be excluded from further analysis as the MFP would be operating unchoked.

Comparing the 16 in. MFP data with and without the boundary-layer trip shows agreement above an area ratio of about 0.5, but deviates significantly below this value. At an area ratio of 0.5, the nozzle Reynolds number is about \(3.0 \times 10^6\). From Figure 9, a Reynolds number of \(3.0 \times 10^6\) is consistent with the end-of-transition implied by the data of Smith and Matz (Ref. 5) and the ASME curve (Ref. 2). Smith and Matz data show a large increase in discharge coefficient below this transition value. Since a fully turbulent nozzle discharge coefficient was used in the 16 in. MFP calibration, which was artificially low for the case with sweeps with no boundary-layer trip, the resulting MFP calibration is under predicted. In fact, what the transitional nozzle discharge coefficient would have been could be estimated by correcting the no-trip data to agree with the tripped data.

A comparison between the adjusted 15 in. MFP and the tripped 16 in. MFP calibration data is shown in Figure 16. The 16 in. MFP calibration data above an area ratio of 0.7 has been removed (ASME nozzle choked) and the remainder of the data was fit with a second order polynomial:

\[
C_{D,plug} = 0.943044 + 0.026915 \cdot AR + 0.017376 \cdot AR^2
\]  

(30)

Also included in this plot are the uncertainty bounds from the general uncertainty analysis. The experimentally determined discharge coefficients for the 15 and 16 in. MFP tend to agree well above an area ratio of 0.6, but deviate below this ratio. In particular, the 16 in. MFP curve does not exhibit the abrupt increase in flow coefficient below an area ratio of 0.2. Inasmuch as the calibration curves lay at the edges of the others uncertainty bounds, this suggests that the differences in calibration are not fully attributable to measurement uncertainties. For both MFPs, the method of calibration produces large uncertainties at low area ratios. This is primarily due to the low Mach number in the ASME nozzle. The use of a delta pressure transducer at low Mach numbers would mitigate the large uncertainties significantly.

As previously mentioned, the numerical study with WIND-US included a numerically based determination of the 16 in. MFP discharge coefficient (see Figure 6 and Figure 7). This study is still in progress and will be reported in a future publication, but the preliminary results indicate a trend very similar to the experimental 16 in. MFP results but shifted up about 0.25 percent. However, results for area ratios below 0.2 have not yet been obtained so no comment can be made regarding the tail-up behavior of the 15 in. MFP.
**Concluding Remarks**

The results of a calibration procedure for the GRC 16 in. MFP have been presented and compared to a previous calibration of a 15 in. MFP. The 16 in. MFP was fabricated from the 15 in. MFP so all future testing will be with the 16 in. MFP. For the 16 in. MFP, a calibration has been established, but a difference in character between the 15 in. MFP and the 16 in. MFP for area ratios below 0.6 is observed. Unfortunately, this region of disagreement coincides with large uncertainty levels. The recommended path forward is to first complete the numerical calibration of the 16 in. MFP; in particular obtaining calibration data below an area ratio of 0.2. And second, the experimental calibration of the 16 in. MFP should be repeated with a focus on minimizing measurement uncertainties.

**References**

The results of an experimental calibration of the NASA Glenn Research Center 16 in. Mass-Flow Plug (MFP) are presented and compared to a previously obtained calibration of a 15 in. Mass-Flow Plug. An ASME low-beta, long-radius nozzle was used as the calibration reference. The discharge coefficient for the ASME nozzle was obtained by numerically simulating the flow through the nozzle from the WIND-US code. The results showed agreement between the 15 and 16 in. MFPs for area ratios (MFP to pipe area ratio) greater than 0.6 but deviate at area ratios below this value for reasons that are not fully understood. A general uncertainty analysis was also performed and indicates that large uncertainties in the calibration are present for low MFP area ratios.
