More than a metric ton of water is transported to the International Space Station (ISS) each year to provide breathing oxygen for the astronauts. Water is a safe and compact form of stored oxygen. The water is electrolyzed on ISS and ambient pressure oxygen is delivered to the cabin. A much smaller amount of oxygen is used each year in spacesuits to conduct Extra Vehicular Activities (EVAs). Space suits need high pressure (>1000 psia) high purity oxygen (must meet Aviator Breathing Oxygen “ABO” specifications, >99.5% O₂). The water / water electrolysis system cannot directly provide high pressure, high purity oxygen, so oxygen for EVAs is transported to ISS in high pressure gas tanks. The tanks are relatively large and heavy, and the majority of the system launch weight is for the tanks and not the oxygen. Extracting high purity oxygen from cabin air and mechanically compressing the oxygen might enable on-board production of EVA grade oxygen using the existing water / water electrolysis system. This capability might also benefit human spaceflight missions, where oxygen for EVAs could be stored in the form of water, and converted into high pressure oxygen on-demand.

Cerium oxide solid electrolyte-based ion transport membranes have been shown to separate oxygen from air, and a supported monolithic wafer form of the CeO₂ electrolyte membrane has been shown to deliver oxygen at pressures greater than 300 psia. These supported monolithic wafers can withstand high pressure differentials even though the membrane is very thin, because the ion transport membrane is supported on both sides (Fig 1). The monolithic supported wafers have six distinct layers, each with matched coefficients of thermal expansion. The wafers are assembled into a cell stack which allows easy air flow across the wafers, uniform current distribution, and uniform current density (Fig 2). The oxygen separation is reported to be “infinitely selective” to oxygen [1] with reported purity of 99.99% [2]. Combined with a mechanical compressor, a Solid Electrolyte Oxygen Separator (SEOS) should be capable of producing ABO grade oxygen at pressures >2400 psia, on the space station.

Feasibility tests using a SEOS integrated with a mechanical compressor identified an unexpected contaminant in the oxygen: water vapour was found in the oxygen product, sometimes at concentrations higher than 40 ppm (the ABO limit for water vapour is 7 ppm). If solid electrolyte membranes are really “infinitely selective” to oxygen as they are reported to be, where did the water come from? If water is getting into the oxygen, what other contaminants might get into the oxygen?

Microscopic analyses of wafers, welds, and oxygen delivery tubes were performed in an attempt to find the source of the water vapour contamination. Hot and cold pressure decay tests were performed. Measurements of water vapour as a function of O₂ delivery rate, O₂ delivery pressure, and process air humidity levels were the most instructive in finding the source of water contamination (Fig 3). Water contamination was directly affected by oxygen delivery rate (doubling the oxygen production rate cut the water level in half). Water was affected by process air humidity levels and delivery pressure in a way that indicates the water was diffusing into the oxygen delivery system. Test results shown in figure
3 suggest that the ion transport membrane does not let any water vapour into the oxygen, but moisture is diffusing through the hot (500-750 degrees C) glass seals that contain the oxygen between the wafers in the cell stack. Water vapour permeation rates are consistent with those reported in the literature [3].

AGENDA

1) Story about a NASA problem
2) Overview of a possible solution
3) Ask for help
4) Microscopy & microanalysis
5) Ask for help
The NASA Problem – Spacesuit Oxygen Tank Recharge

- The EMU has two types of oxygen tanks
  - Primary oxygen tanks that are filled to about 900 psig
  - Secondary (emergency) oxygen tanks that are filled to about 6000 psig
- The Primary tanks are filled from an airlock oxygen tank before each spacewalk
- The Secondary tanks have never been used in flight – they are not recharged in space
The NASA Problem – Spacesuit Oxygen Tank Recharge

- The NASA airlock on ISS has 4 external oxygen tanks – 3 are connected, one is a spare
The NASA Problem – Spacesuit Oxygen Tank Recharge

- When the Shuttle was flying, the ISS oxygen tanks were recharged with shuttle cryogenic $O_2$. 
The NASA Problem – Spacesuit Oxygen Tank Recharge

- With Shuttle gone, NASA can’t use Shuttle derived cryogenic O₂ to recharge airlock tanks
- For exploration, cryogenic tanks tend to boil away
- Transporting oxygen as a high pressure gas requires a large and heavy system

Possible Solution – Solid Electrolyte Oxygen Separator (SEOS)

- We already transport (safe, dense) water to the International Space Station
- We already electrolyze the water to make low pressure oxygen
  - That is immediately mixed with cabin air and diluted
- SEOS can produce high purity oxygen from cabin air
- SEOS would allow exploration missions to store oxygen in the form of water, electrolyze water at low pressure, and still have high pressure, high purity oxygen for spacesuits
What is a SEOS and how does it work?

- SEOS takes room air, heats it, applies a dc current across a ceramic, and the oxygen is pumped into a product line.

Operating Principle:

Some ceramics electrochemically pump oxygen at high temperatures when a DC potential is applied.
What is a SEOS and how does it work?

- This particular SEOS uses a monolith wafer – oxygen can be produced at >300 psi

Ask for Help

- Trace amounts of moisture (10-40 ppm) are getting into the oxygen stream
- The moisture is almost certainly getting through the SEOS ceramic layer
- The moisture almost certainly is permeating through the glass seal between the monolith layers

- HOW CAN WE STOP THE WATER FROM GETTING INTO THE OXYGEN?

Ask for Help

• Trace amounts of moisture (10-40 ppm) are getting into the oxygen stream
• The moisture is almost certainly getting through the SEOS ceramic layer
• The moisture almost certainly is permeating through the glass seal between the monolith layers

• HOW CAN WE STOP THE WATER FROM GETTING INTO THE OXYGEN?
Summary

• SEOS systems may provide spacesuit grade oxygen for ISS and exploration missions
• Microscopy and many trials made the SEOS monolith wafer possible
• The SEOS system is presently more complicated than it needs to be – can you tell us how to minimize water contamination?
