ABSTRACT

We present spectrally resolved observations of the young multiple system T Tau in atomic and molecular lines obtained with the Heterodyne Instrument for the Far Infrared on board Herschel. While CO, H2O, [C II], and SO lines trace the envelope and the outflowing gas up to velocities of 33 km s−1 with respect to systemic, the CN 5–4 hyperfine structure lines at 566.7, 566.9 GHz show a narrow double-peaked profile centered at systemic velocity, consistent with an origin in the outer region of the compact disk of T Tau N. Disk modeling of the T Tau N disk with the thermo-chemical code ProDiMo produces CN line fluxes and profiles consistent with the observed ones and constrain the size of the gaseous disk (Rout = 110±10 AU) and its inclination (i = 25°±5°). The model indicates that the CN lines originate in a disk upper layer at 40–110 AU from the star, which is irradiated by the stellar UV field and heated up to temperatures of 50–700 K. With respect to previously observed CN 2–1 millimeter lines, the CN 5–4 lines appear to be less affected by envelope emission, due to their larger critical density and excitation temperature. Hence, high-J CN lines are a unique confusion-free tracer of embedded disks, such as the disk of T Tau N.

Key words: astrochemistry – ISM: molecules – protoplanetary disks – stars: individual (T Tau)

Online-only material: color figures

1. INTRODUCTION

The study of the physical and chemical structure of protoplanetary disks is crucial to comprehend the formation of planetary systems. According to models, disks have a stratified structure, and hence different molecular species probe the physical and chemical conditions of different layers from the warm irradiated surface down to the cold midplane. Disks around non-embedded systems include a number of other millimeter (mm) and submillimeter molecular lines (e.g., Dutrey et al. 1997; Thi et al. 2004). On the contrary, the study of disks around more embedded systems is obstructed by the associated envelopes and outflows which also emit strongly in the same molecular lines, hiding the fainter disk emission.

Recent studies show that CN is a good disk tracer with 88% of the T Tauri disks detected in CO 2–1 which are also observed in the CN 2–1 lines (Öberg et al. 2010, 2011; Chapillon et al. 2012). Moreover, Guilloteau et al. (2013) performed an IRAM 30-m survey of T Tauri and Herbig Ae systems located mainly in the Taurus-Auriga region and show that the CN 2–1 lines are less affected by the emission from the surrounding molecular cloud than the lines from CO isotopologues. However, CN 2–1 lines are still dominated by envelope/outflow emission in the case of actively accreting/ejecting sources, such as T Tau.

T Tau is a multiple system driving at least two bipolar jets detected in optical, near-infrared forbidden lines (Bohm & Solf 1994; Eisloffel & Mundt 1998; Solf & Böhm 1999; Herbst et al. 2007). The system consists of the northern component T Tau N (M∗ = 2.1 M⊙) and of the binary system T Tau Sa+Sb located 0′′7 to the south (Mi = 2.1, 0.8 M⊙, separation Sa–Sb = 0′′13; Köhler et al. 2008). T Tau N is optically visible and is surrounded by an almost face-on, intermediate mass disk (i < 30°, Mdisk ∼ 0.01 M⊙) and an optically thin envelope (Beckwith et al. 1990; Hogerheijde et al. 1997; Akesson et al. 1998; Ratzka et al. 2009; Guilloteau et al. 2011). Both southern components, instead, are strongly obscured (AV ≳ 15, 30 mag toward T Tau Sb and Sa, respectively), possibly due to a circumbinary envelope and, for T Tau Sa, to its almost edge-on disk (i ∼ 72°; Duchêne et al. 2005; Ratzka et al. 2009). Sa and Sb are not detected at mm wavelengths suggesting that their disks are small and of low-mass (Mdisk ∼ 10−5–10−3 M⊙, Rout ∼ 5 AU; Hogerheijde et al. 1997; Ratzka et al. 2009). While the dusty disk of T Tau N has been mapped in the mm, there are only tentative observations of its gaseous disk, e.g., in the H2 near-infrared lines (Gustafsson et al. 2008). Emission in the [O I] 63 µm, [C II] 157 µm, and [Ne II] 12.81 µm lines is extended.
and/or velocity-shifted, and hence likely associated with outflowing gas, while molecular lines, such as high-J CO, OH, and H2O lines, are spectrally and spatially unresolved (Spinoglio et al. 2000; van Boekel et al. 2009; Podio et al. 2012). Observations of H2O lines, are spectrally and spatially unresolved (Spinoglio et al. 16) to high-J CO, 13CO, C17O, o-H2CO, SO, and CN 2–1 are also dominated by outflowing gas, while molecular lines, such as high-J CO, OH, and [CII] lines in the mm range obtained with the Heterodyne Instrument for the Far Infrared (HIFI) on board Herschel. While CO, 13CO, H2O, [CII], and SO lines are still strongly dominated by emission from the surrounding envelope and outflows, the CN 2–1 lines allow digging out the faint emission from the disk of T Tau N.

2. OBSERVATIONS AND DATA REDUCTION

We observed T Tau at $v_{\text{up}} = 0d_{2000}^{1b}21^{m}59^{s}4, \delta_{2000} = +19^{\circ}32'06''/4$ with the HIFI (de Graauw et al. 2010) on board the Herschel Space Observatory16 (Pilbratt et al. 2010). The observations target the two fundamental water lines, o-H2O 10–101 and p-H2O 11–000 in the HIFI bands 1 and 4, the 12CO (hereafter CO) 10–9 line in band 5, and the [CII] line in band 7 (OBSID: 1342249419, 1342250207, 1342249598, 1342249647). They were acquired with a single on-source pointing and in dual beam switch mode with fast chopping 3° either side of the target. The achieved rms noise in bands 1, 4, 5, 7 is of 6, 8, 7.5, 83 mK, respectively. The Wide Band Spectrometer (WBS) and the High Resolution Spectrometer were used in parallel, providing a spectral resolution of 1.10 and 0.25 MHz, respectively. The half power beam width (HPBW) ranges from ~11° to ~38°, depending on frequency. Hence, all the three sources of the T Tau system (N, Sa, and Sb) are covered by the observations. The selected spectral settings also cover with the WBS the CN 5–4 $J = 9/2–7/2$ and $J = 11/2–9/2$, SO 1213–1112, 13CO 10–9, and o-H2O 312–221 lines.

The HIFI data were reduced using HIPE 10.17 Fits files from level 2 were then created and transformed into GILDAS18 format for data analysis. The spectra were baseline subtracted and averaged over the horizontal and vertical polarization to increase the signal-to-noise ratio. Antenna temperatures, $T_a$, were converted to mean beam temperature, $T_{mb}$, using mean beam efficiency by Roelfsema et al. (2012).

The properties of the detected lines (transition, frequency, $v_0$, upper level energy, $E_{up}$), the HPBW, and the measured parameters (peak temperature and velocity, $T_{peak}$ and $V_{peak}$, the full line width at 1σ rms noise, $\Delta V$, integrated intensity, $\int T_{mb}dV$, and line fluxes, $F_{obs}$) are summarized in Table 1.

19 $F_{obs} = (2K_{b}c^{-3}) \times \int T_{mb}dV \times \pi (\text{HPBW}/2\sqrt{ln2})^{3}$. 

---

2
We also detect three water lines: the $^{16}$O$\text{H}_2\text{O}$ $1_0-10_1$, $^{18}$O$\text{H}_2\text{O}$ $3_{12}-2_{21}$, and $^{2}$H$\text{H}_2\text{O}$ $1_{11}-0_{00}$ lines. The two fundamental water lines ($E_{\text{up}} \sim 61, 53$ K) show an absorption feature at the systemic velocity, due to the cloud, and a second absorption at $\sim 4.5$ km s$^{-1}$, whose origin is unclear. As already observed in previous works (e.g., Kristensen et al. 2012), water lines appear to be very sensitive to high-velocity emission showing wings extending up to velocities of $\sim 12$ km s$^{-1}$ and $\pm 40$ km s$^{-1}$.

In contrast with previous observations of CO 6–5, 3–2, 2–1, and 1–0 lines (Edwards & Snell 1982; Schuster et al. 1993), the observed CO 10–9, $^{12}$CO 10–9, and [C ii] lines show a red-shifted wing which is brighter and extends to higher velocities than the blue one. The lines observed with HIFI have higher upper level energies and/or critical densities than previously observed low-J CO lines ($E_{\text{up}} \lesssim 116$ K), thus suggesting that the red-shifted outflowing gas is denser and more excited than the blue-shifted gas.

Our observations also cover the CN $N = 5–4$ hyperfine structure lines²⁰ (Müller et al. 2001). We detect the three brightest $J = 9/2–7/2$ and $J = 11/2–9/2$ lines at 566.7 GHz and 566.9 GHz, while the fainter $J = 9/2–9/2$ components fall outside the observed range. The separation in velocity between the three detected lines is between 0.05 and 0.45 km s$^{-1}$, and hence the lines are not resolved at the available resolution (0.5 km s$^{-1}$) and the observed profile is sensitive only to the kinematics of the emitting gas. The CN $5–4$ $J = 9/2–7/2$ lines show a narrow double-peaked profile centered at the systemic velocity with a total line width of $\sim 7$ km s$^{-1}$, FWHM of $\pm 0.5$ km s$^{-1}$, and a peak separation $\Delta V_{\text{sep}} = 2.4 \pm 0.5$ km s$^{-1}$. The profile of the $J = 11/2–9/2$ blended components is also narrow and symmetric around the systemic velocity, even though the double-peak is not as clear as in the $J = 9/2–7/2$ lines (see Table 1). The blue-redshifted wing shown by the $J = 9/2–7/2$ and the $J = 11/2–9/2$ components, respectively, is clearly due to the noise at it is below the noise level and is not detected in both components. Hence, the CN $5–4$ profiles are consistent with emission from the outer region of the disk of T Tau N. The double-peak detected in the CN $5–4$ lines is not seen in the $2–1$ lines observed with the IRAM 30-m by Guilloteau et al. (2013). This is due to the higher excitation energy and critical density of the CN $5–4$ lines ($E_{\text{up}} \sim 82$ K, $n_{\text{up}} \approx 2 \times 10^8$ cm$^{-3}$), which makes them less affected by cloud emission, hence more effective to probe the disk, than CN $2–1$ ($E_{\text{up}} \sim 16$ K, $n_{\text{up}} \approx 2 \times 10^7$ cm$^{-3}$). Emission from the disks of T Tau Sa and T Tau Sb is expected to be negligible with respect to the emission from the disk of T Tau N, as those disks are not detected in the mm continuum and are one to two orders of magnitude less massive and very small (Akeson et al. 1998; Ratzka et al. 2009; Guilloteau et al. 2011).

Assuming Keplerian rotation, a stellar mass of 2.1 $M_\odot$ and an inclination of $i \sim 20^\circ–30^\circ$ (Ratzka et al. 2009), the peak separation of the CN lines indicates an outer disk radius $R_{\text{ou}}(\text{CN}) < 160–350$ AU. This upper limit is in agreement with the size of the disk as estimated from continuum maps at 1.3, 2.7 mm ($R_{\text{ou}}(\text{dust}) = 67 \pm 20$ AU, Guilloteau et al. 2011) and from the H$2$ ring-like structure observed by Gustafsson et al. (2008) ($R_{\text{ou}}(\text{H}_2) = 85–100$ AU).

4. MODELING CN LINES FROM THE DISK OF T Tau N

In order to test if the CN lines originate in the disk of T Tau N we use a parameterized disk model calculated with the

---

²⁰ Due to the coupling of the rigid-body angular momentum, $N$, with the electronic spin, $S$, and with the nuclear spin, $I$, angular momenta, the CN $N = 5–4$ line is split into 19 hyperfine components characterized by the corresponding quantum numbers $J = N + S$, and $F = J + I$.  

Figure 1. Herschel/HIFI spectra of CN 5–4 9/2–7/2 (panel (a)), CN 5–4 11/2–9/2 (panel (b)), o-$^2$H$_2$O 3–2 (panel (c)), p-$^2$H$_2$O 11/2–9/2 (panel (d)). Horizontal and vertical dotted lines indicate the baseline and systemic velocity ($V_{\text{sys}} = \pm 7.7$ km s$^{-1}$). The line frequency, HPBW, and upper level energy are labeled. For CN 5–4 the rms noise is indicated by the dashed horizontal line and the positions of the hyperfine structure lines by the red vertical lines. The line profiles predicted by the ProDiMo disk model of T Tau N are overplotted in black, magenta, and blue (corresponding observed profiles are in gray, magenta, and blue). (A color version of this figure is available in the online journal.)
As the CN line fluxes and profiles are very sensitive to the assumed disk outer radius, \( R_{\text{out}} \), and inclination, \( i \), we proceed through two steps. First, we run a grid of models at low resolution (50 \times 50 grid points) adopting \( R_{\text{out}} \) and \( i \) values which cover the range of estimates from previous studies (\( R_{\text{out}} = 67, 90, 100, 110, 120 \) AU, \( i = 20, 25, 30, 35, 40, 45 \) AU; Stapelfeldt et al. 1998; Gustafsson et al. 2008; Ratzka et al. 2009; Guilloteau et al. 2011; Harris et al. 2012). Then, we run a high resolution model (100 \times 100 grid points) for \( R_{\text{out}} \) and \( i \) which best fit the observations, to better resolve the chemical and temperature gradients and the vertical extent of the line forming region in the disk. The predicted FWHM and peak separation do not depend on the model resolution while the line fluxes are lower by up to \( \sim 30\% \) when increasing the resolution.

The line profiles and fluxes are obtained by first solving the statistical equilibrium with two-dimensional escape probability to obtain the level populations, and then using two-dimensional ray-tracing. As the three brightest lines of each CN 5–4 \( J' \rightarrow J' \) transition are blended and the three undetected components are more than one order of magnitude fainter, the model computes the sum of the CN 5–4 \( J = 9/2 \rightarrow 7/2 \) and \( J = 11/2 \rightarrow 9/2 \) lines. The results obtained for the grid of models (Figure 2) show that the CN line fluxes depend mainly on the disk size and the vertical extent of the line forming region in the disk.

As suggested by their profiles, the CN lines originate from the outer region of the disk. The best fit of the CN line fluxes is obtained for \( R_{\text{out}} = 100–110 \) AU. However, as model-predicted fluxes are affected by \( \sim 30\% \) uncertainty, values of \( R_{\text{out}} \) between 90 and 120 AU produce CN line fluxes which are still in agreement with the observations. The ratio between the 566.9 and the 566.7 GHz lines predicted by the models, \( R_{\text{mod}} = 1.2 \), is slightly lower but still in agreement with the observed one (\( R_{\text{obs}} = 1.4 \pm 0.2 \)). The peak separation and

**Figure 2.** Observed line properties (in red) are compared with model predictions (in black) for different values of the disk outer radius, \( R_{\text{out}} \) (AU), and inclination, \( i \), for the CN 5–4 \( J = 9/2 \rightarrow 7/2 \) and \( J = 11/2 \rightarrow 9/2 \) lines (top and bottom panel, respectively). The peak separation vs. the line flux is overplotted with empty circles and dotted lines. (A color version of this figure is available in the online journal.)
FWHM predicted by the models depend on both $R_{\text{out}}$ and $i$. For $R_{\text{out}} = 90–120$ AU the observed $\Delta V_{\text{ep}}$ and FWHM are reproduced if the disk inclination is low ($i = 20^\circ - 30^\circ$). This is in agreement with the conclusions by Akeson et al. (2002) and Ratzka et al. (2009) based on the modeling of theSED and near-, mid-infrared visibilities. Larger inclination angles of $40^\circ - 45^\circ$ (Stapelfeldt et al. 1998; Guilloteau et al. 2011) are excluded based on the observed CN profiles.

Following the results obtained from the grid of models, we adopt $R_{\text{out}} = 110$ AU, $i = 25^\circ$ and compute the fluxes and profiles of all the lines covered by our observations using the high resolution model. Figure 3 shows the region in the disk where 50% of the CN 5–4 $J = 9/2$–7/2 and J = 11/2–9/2 lines originate according to our model. This is obtained using vertical escape probability and without accounting for disk inclination. The model indicates that the CN lines are excited in a disk upper layer located at 40–110 AU distance from the star, which is irradiated by the stellar UV field. This heats the gas up to temperatures of $\sim 50–700$ K, while the gas density is $\sim 10^7–3 \times 10^8$ cm$^{-3}$, thus the CN lines are almost thermalized and optically thick ($r \sim 10^2–10^3$) in the line emitting region. In this disk layer, CN is produced by H + CN$^+$, and C + NO reactions, and photo-dissociation of HCN, while the main destruction route is photo-dissociation of CN.

In Figure 1 and Table 1, the model-predicted line profiles and fluxes are compared with the observed ones. For CN lines, the model predicts an FWHM of 3.9 km s$^{-1}$ and peak separation of 2.6 km s$^{-1}$, in agreement with observations (FWHM = 4.0, 4.2 ± 0.5 km s$^{-1}$, $\Delta V_{\text{ep}} = 2.4$, 2.1 ± 0.5 km s$^{-1}$). Also the line fluxes agree with observations within a factor $\sim 0.9$, 1.2. The sum of the fluxes of the $N = 2$–1 components, instead, is about an order of magnitude lower than what observed by Guilloteau et al. (2013), who suggest that the line is dominated by envelope emission. The CO, $^{13}$CO, H$_2$O, and SO line fluxes predicted by the disk model are from a factor four to two orders of magnitude smaller than observed, as well as for the high-J CO, H$_2$O, OH, and atomic [O i], [C ii] lines previously observed with PACS (see Table 4 by Podio et al. 2012). This is a further evidence that these lines are dominated by envelope and outflow emission, as already suggested by the fact that [O i], [C ii] emission is spatially extended with PACS ($\gtrsim 9''$) and by the broad profiles of CO, H$_2$O, SO, and [C ii] obtained with HIFI.

5. CONCLUSIONS

The Herschel/HIFI observations of the T Tau system show emission in a number of molecular and atomic lines. The origin of the emission lines in embedded, accreting ejecting sources is highly debated, being crucial to identify a tracer to dig out the faint disk emission (e.g., Podio et al. 2012, 2013). In the case of T Tau, the CO, H$_2$O, and [C ii] lines clearly trace high-velocity outflowing gas. By contrast with those lines and with previously observed CN 2–1 lines (Guilloteau et al. 2013), the CN 5–4 lines show narrow double-peaked profiles centered at the systemic velocity, suggesting an origin in the outer disk of T Tau N. Disk modeling predicts CN line fluxes and profiles in agreement with observed ones and constrains the size of the gaseous disk of T Tau N ($R_{\text{out}} = 110^{+0.10}_{-0.05}$ AU) and its inclination ($i = 25^\circ ± 5^\circ$). This study demonstrates that high-J CN lines are a unique tool to probe the gaseous disk of strongly accreting/ejecting sources and paves the way for future observations of embedded disks with ALMA.
