Abstract

Background: The role of meteorological factors on influenza transmission in the tropics is less defined than in the temperate regions. We assessed the association between influenza activity and temperature, specific humidity and rainfall in 6 study areas that included 11 departments or provinces within 3 tropical Central American countries: Guatemala, El Salvador and Panama.

Method/Findings: Logistic regression was used to model the weekly proportion of laboratory-confirmed influenza positive samples during 2008 to 2013 (excluding pandemic year 2009). Meteorological data was obtained from the Tropical Rainfall Measuring Mission satellite and the Global Land Data Assimilation System. We found that specific humidity was positively associated with influenza activity in El Salvador (Odds Ratio (OR) and 95% Confidence Interval of 1.18 (1.07-1.31) and 1.32 (1.08-1.63)) and Panama (OR = 1.44 (1.08-1.93) and 1.97 (1.34-2.93)), but negatively associated with influenza activity in Guatemala (OR = 0.72 (0.6-0.86) and 0.79 (0.69-0.91)). Temperature was negatively associated with influenza in El Salvador’s west-central departments (OR = 0.80 (0.7-0.91)) whilst rainfall was positively associated with influenza in Guatemala’s central departments (OR = 1.05 (1.01-1.09)) and Panama province (OR = 1.10 (1.05-1.14)). In 4 out of the 6 locations, specific humidity had the highest contribution to the model as compared to temperature and rainfall. The model performed best in estimating 2013 influenza activity in Panama and west-central El Salvador departments (correlation coefficients: 0.5–0.9).

Conclusions/Significance: The findings highlighted the association between influenza activity and specific humidity in these 3 tropical countries. Positive association with humidity was found in El Salvador and Panama. Negative association was found in the more subtropical Guatemala, similar to temperate regions. Of all the study locations, Guatemala had annual mean temperature and specific humidity that were lower than the others.
Introduction

Influenza is estimated to infect approximately 1 billion people each year with 3 to 5 million severe cases and up to 500,000 deaths worldwide [1,2]. Influenza epidemics typically occur during winter months in temperate regions. In contrast, the timing of influenza epidemics in the tropics varies and often cannot be easily defined because of insufficient surveillance, multiple annual epidemics [3], or continuous influenza activity throughout the year [4]. Several studies have suggested an association between the environment or climate with influenza transmission because of the apparent spatiotemporal variation in influenza spread [5–9].

Temperature and relative humidity (RH) have been linked to influenza virus survivability [10–12]. A recent study also showed that the stability of the virus outer membrane, which possibly provides protection for the virus during airborne transmission, depends on temperature [13]. In addition, Lowen et al. [8] showed in a laboratory experiment that virus shedding in guinea pigs was significantly longer in low temperatures. Findings on the relationship between influenza transmission and RH were less consistent [14]: Some studies found that aerosolized virus survival decreased as RH increased, while others showed a two-mode relationship. Meanwhile, Shaman and Kohn [9] argued that absolute humidity (AH) influenced influenza virus survival and transmission efficiency more significantly than RH. The associations between influenza and low temperature and humidity have mostly been observed in temperate regions [15,16]. But in the tropics, where the annual average of temperature and humidity are normally higher than those in the temperate regions, insufficient evidence exists for such a relationship. Nevertheless, the monthly proportion of influenza positive in a few tropical and subtropical countries seemed to be associated with low temperature [3]. In addition, influenza transmission in the tropics often coincides with the rainy season when absolute humidity is typically at its highest [17].
In the tropics, several regions including northeastern Brazil, Philippines and the western part of India, had high influenza activity during the rainy season [18,19], but others had semi-annual peaks that are not necessarily associated with rainfall [20]. The direct relationship between rainfall and influenza has yet to be established. It is postulated that rainfall leads to crowding which in turn increases the probability for contact, droplet and aerosol transmission. An experimental study [21] showed that contact transmission, unlike aerosol-borne transmission, remained efficient at 30°C. This study also suggested that contact or very close-range transmission may predominate in the tropics, and that more studies are needed to elucidate the transmission route of influenza in the tropics.

In Central America, influenza surveillance data has been limited and the role of environmental and climatic factors on influenza transmission has not been studied. In an effort to comply with the 2005 International Health Regulations, several countries in Central America initiated influenza pandemic preparedness and response plans during 2006. In the same year, countries in Central America also introduced the Generic Protocol for Influenza Surveillance [22] in order to strengthen influenza surveillance [23]. By 2010, this program already showed a significant improvement in influenza surveillance, as evidenced by the expansion of sentinel surveillance networks and the tenfold increase in the number of samples reported by National Influenza Centers (NIC’s) to the World Health Organization Global Influenza Surveillance and Response System [24].

This increased surveillance capacity in the region has provided a better depiction of the respiratory viruses prevalence throughout the year. The countries in Central America now detect respiratory virus in more than 15–20% of samples tested each month – although the periodicity and intensity are different in each country [25]. For example, in Panama, Nicaragua and El Salvador, influenza epidemics occur in a pattern similar to those of southern hemisphere where the epidemics usually occur at mid-year. In other countries such as Costa Rica, Honduras and Guatemala, influenza activity may also occur to a lesser extent during winter months (December to February) [26], although there can be larger variations in Guatemala. In this study, we used data from the improved influenza and other respiratory virus surveillance systems in El Salvador, Guatemala and Panama.
to explore the association between weekly proportions of surveillance samples tested positive for influenza and temperature, rainfall and specific humidity.

**Materials and Methods**

**Study Area**

We used influenza surveillance data collected from 11 departments or provinces in 3 Central America countries (Figure 1). These included 4 departments in Guatemala: San Marcos, Quetzaltenango, Guatemala and Santa Rosa; 5 departments in El Salvador: Santa Ana, La Libertad, Cuscatlán, San Salvador and San Miguel; and 2 provinces in Panama: Chiriquí and Panama. To have larger influenza sample sizes, we combined adjacent departments in Guatemala and El Salvador. The combined study areas included western Guatemala departments (San Marcos and Quetzaltenango), central Guatemala departments (Guatemala and Santa Rosa) and west-central El Salvador departments (Santa Ana, La Libertad, San Salvador and Cuscatlán). Other departments or provinces, including San Miguel Department in El Salvador and both Chiriquí and Panama Provinces in Panama – were analyzed individually. Overall, there were 6 study locations.

According to the Köppen climate classification [27] which is based on temperature, precipitation and natural vegetation, these three countries have a tropical wet and dry (savanna) climate. Climate in this zone generally has mean temperature above 18°C year-round and a pronounced dry season. However, there are substantial variations in climate across the region. Most of the cities in Guatemala are located in the mountainous highlands formed by Sierra Madre, the Cuchumatanes range and other sierras. The climate on the highlands is subtropical, and cooler and drier than the rest of Guatemala. Both Panama and El Salvador have less varied topography and are at lower elevation than Guatemala.
Virological Data

We obtained influenza surveillance data from National Influenza Centers (NIC) at the Gorgas Memorial Institute for Health Studies in Panama [28], the Dr. Max Bloch National Laboratory of the Ministry of Health of El Salvador [29], and the National Laboratory of the Ministry of Public Health of Guatemala [30]. Each NIC compiled and tested respiratory samples from the country’s sentinel surveillance system, which is composed of ambulatory clinics and hospitals. There are 9 participating clinics and hospitals in western Guatemala departments, 5 in central Guatemala departments, 13 in west central El Salvador departments, 3 in San Miguel Department in El Salvador, 3 in Chiriquí Province in Panama and 9 in Panama Province [31]. Samples were taken from influenza-like illness (ILI) case-patients in the clinics, and severe acute respiratory infection (SARI) case patients in the hospitals. In all 3 countries, ILI was defined according to WHO criteria [31]: sudden onset of a fever >38°C, either cough or sore throat, and an absence of other diagnoses. SARI case-patient for children under 5 years old was defined as any child <5 years old who was clinically suspected of having pneumonia or severe/very severe pneumonia, and requiring hospitalization [31]. For persons older than 5 years old, SARI was defined as a sudden onset of fever >38°C, either cough or sore throat, shortness of breath or difficulty of breathing, and requiring hospital admissions [31]. Each clinic and hospital selected a convenience sample of case-patient (about 5 samples per week). Influenza was identified using indirect immunofluorescence, and starting in 2009 subtyped through reverse transcription polymerase chain reaction (RT-PCR) [31,32]. Other respiratory viruses that were also identified using RT-PCR included respiratory syncytial virus (RSV), parainfluenza viruses and adenoviruses. Influenza data in each department or province was collected for at least 3 years, ending in July 2013 (Table 1). In the analysis, we excluded influenza data during the pandemic year period (2009) when influenza transmission was atypical.
Meteorological Data

The meteorological data for the analysis was obtained from the Tropical Rainfall Measuring Mission (TRMM) satellite and the Global Land Data Assimilation System (GLDAS) [33,34]. In another study on associating influenza activity in other countries with meteorological variables, we also used meteorological data from ground stations [35]. For the study locations in these 3 countries, however, ground stations were sparsely distributed and their measurements had extensive gaps throughout the study period. Therefore, we did not use ground station data in this study. All meteorological variables in this study were obtained for the same time period as the influenza data.

Rainfall measurements from the Tropical Rainfall Measuring Mission (TRMM) satellite were downloaded via NASA’s Goddard Earth Sciences and Data Information Service Center (GES-DISC) Interactive Online Visualization And Analysis Infrastructure (GIOVANNI)[36]. We used the daily precipitation product (TRMM 3B42) with 0.25° by 0.25° spatial resolution (~25 km at the equator) and a geographical coverage of 50°S–50°N. We averaged all pixels that had more than 10% of its footprint within the study region. Subsequently we took the weekly average in order to match the influenza data temporal resolution.

As a measure for humidity, we obtained specific humidity data. Briefly, specific humidity is the ratio between mass of water vapor and the mass of air (typically expressed in g/kg). It is a similar measure as absolute humidity (please see Supplementary Information for a more detailed description of specific humidity). Near surface specific humidity and temperature for all study locations were obtained from the Global Land Data Assimilation System (GLDAS)[33]. GLDAS is a NASA-NOAA system that utilizes ground and satellite measurements to model global terrestrial geophysical parameters with contiguous spatial and temporal coverage. This dataset also had 0.25° by 0.25° spatial resolution and 3-hourly temporal resolution. Similarly, to obtain the weekly time series for each study region we first averaged the pixels followed by averaging the 3-hourly data into daily data.
All daily meteorological variables were averaged over each week and over two to four previous weeks (i.e. average from the current week to the previous 2 weeks).

Analysis

Taking into account the influenza surveillance systems in the 3 Central American countries, we calculated the weekly proportion of respiratory samples that were tested positive for influenza virus to represent influenza activity. The commonly used indicator for influenza activity, especially for developed countries in temperate climate zone with established influenza systems, is based on the number of pneumonia and influenza (P&I) mortality, the number of ILI or ARI case patients, or the number of respiratory samples tested positive for influenza viruses. However, such an indicator is not the most suitable for the countries in this study for the following reasons. When using mortality and morbidity data, influenza activity is usually obtained by applying seasonal regression, such as Serfling regression [37]. This approach is not suitable for subtropical countries where influenza activity often does not have a clear seasonal pattern as in the temperate regions. Another estimate of influenza morbidity can also be obtained by multiplying the ILI or SARI cases with the proportion of samples tested positive for influenza. However, the total number of health seeking ILI or SARI cases is not routinely or systematically collected, and therefore not yet part of the surveillance practice in all of the departments or provinces in this study. In the developed countries, large number of ILI or ARI cases are tested for influenza during influenza seasons, hence the number of samples tested positive can, by itself, be used as an influenza indicator. In the three Central American countries in this study, the surveillance systems are nascent and evolving, and only a small proportion of case patients were tested because of the limited throughput of influenza laboratories. Therefore, absolute number of laboratory confirmed influenza cases does not represent the timing of influenza activity well. In the operational setting, influenza positive proportion has been used to determine the influenza timing in Central America. With scant influenza surveillance data available, the proportion of respiratory samples tested positive for influenza (hereafter referred as the “influenza positive
proportion”) was considered the most suitable measure to represent influenza activity for the 3 countries in this study. Several influenza studies had also used influenza positive proportion as influenza indicator [3,38–40].

We used logistic regression to model the weekly influenza positive proportion. The logistic regression can model strictly bounded response variable, and is commonly used to describe data on proportions [41]. Other epidemiological studies have used logistic regression to link the disease prevalence with climatic variables [42,43]. We applied logit function to the influenza positive proportion. Such a function describes a scenario where as the meteorological conditions become more favorable for influenza transmission, more people will be infected, and more specimens will likely be tested positive for influenza. Consequently the odds (logit) for influenza-positive will increase. We performed the logistic regression in R software [44], and we used the methods delineated in [41] to formulate the model for count proportion data where both the influenza positive and negative counts were supplied to the model. More details on this method can be found in the Supplementary Information.

The regression model was fitted individually to each study region using the associated data from the entire study period except for the final year (year 2013), which was reserved for validation. The explanatory variables considered in the regression model were the meteorological variables (temperature, specific humidity and rainfall), positive proportion of other respiratory viruses that co-circulated with influenza (RSV, parainfluenza viruses and adenoviruses), lagged dependent variables (up to lag of 4 weeks), and a polynomial function of the week number (up to degree of 3: week, week\(^2\), week\(^3\), where week = 1, 2, 3,… 52). Several studies had found associations between the co-circulating viruses (RSV, parainfluenza virus and adenovirus) and meteorological factors including temperature and rainfall in the tropics [20,45]. Therefore these viruses were included to adjust for any potential confounding associations between influenza and the meteorological variables. The lagged dependent variable was included since the amount of influenza activity in a particular week depended on the previous week’s activity, and also to account for autocorrelation. The week number was included to
represent influenza seasonality and other nonlinear relationships that were not
represented by the 3 meteorological variables. We first tested the full model as described
above. A backward selection (see Supporting Information, Text S1, for details) was then
applied to select the polynomial order of the week number and the lagged dependent
variable, resulting in a reduced model. Autocorrelation was assessed by inspecting the
autocorrelation function (ACF) and partial autocorrelation function (PACF) plots.
Collinearity among the covariates was assessed by calculating the variance inflation
factor (VIF), which is a factor of how much the coefficient’s standard error would
increase if the said covariate were not correlated with the others. We further tested the
full model with different meteorological lags and average periods, resulting in 11
different models. The best model was then selected based on the Akaike’s Information
Criterion (AIC) (see Supporting Information, Text S1, for more details). We did not
include interaction terms between predictors because of possible multi-collinearity and
lack of clear geophysical interpretations for such terms.

In addition to presenting the Odds Ratio (OR) of the meteorological variable, we also
calculated the change in the influenza positive proportion each week when the significant
meteorological variables were increased by one standard deviation. We used this measure
because it was easier to interpret in terms of the positive proportion rather than the odds
for the positive proportion. The change in influenza positive proportion was calculated
using meteorological observations throughout the study period. Lastly, to assess the
relative contribution of each meteorological variable, we calculated the change in the
model deviance when one meteorological variable was removed at a time (more details in
the Supporting Information, Text S1). This change in deviance is a proxy for the relative
contribution of each meteorological variable.

A more detailed description of the method can be found in the Supporting Information
(Text S1). All statistical analysis was performed using R software [44].
Results

Influenza data was collected from 2008 to 2013, except for two locations (Table 1): El Salvador’s San Miguel Department (2010 to 2013) and Guatemala’s western departments (2009 to 2013). During the study periods (excluding the 2009 pandemic year), the proportion of respiratory samples that was tested positive for influenza (influenza positive proportion) in all study locations ranged from 9.67% to 19.85% (Table 1). Similarly, RSV positivity ranged from 7.19% to 20.96%; whereas positivity for adenoviruses and parainfluenza viruses was lower (1.28–8.09% and 0.34–6.66% respectively).

In all locations except for Guatemala, the mean temperature during study period was above 22°C. The mean temperature in Guatemala’s western departments was the lowest of all study locations (17.65°C), followed by Guatemala’s central departments (20.38°C). Panama Province had the highest mean temperature throughout the study period. Similarly, average specific humidity was the lowest in Guatemala departments, and the highest in Panama. Mean precipitation rate throughout the study period was the highest in Panama (9.04 mm/day in Chiriquí Province, 6.68 mm/day in Panama Province), and the lowest in Guatemala’s central departments.

In the analysis, we tested the associations between influenza positive proportion and 3 meteorological inputs (temperature, specific humidity and rainfall), while adjusting for co-circulating viruses (RSV, adenoviruses and parainfluenza viruses), week number, and lagged dependent variables. Eleven models which differed in the meteorological lags and average periods were tested for each study location. The best models (Table 2) were selected based on the AIC. From the best models, we found that influenza positive proportion was significantly associated (p<0.05) with specific humidity in all study locations, whereas significant association with temperature and rainfall were location-specific (Table 2). Specific humidity was positively associated with influenza positivity in west-central departments (Odds Ratio (OR) 1.18, 95% Confidence Interval (CI) 1.07-1.31) and San Miguel (OR 1.32, 95% CI 1.08-1.63) of El Salvador, and Chiriqui Province (OR 1.97, 95% CI 1.34-2.93) and Panama Province (OR 1.44, 95% CI 1.08-1.93) of
Panama, but negatively associated with influenza activity in central (OR 0.79, 95% CI 0.69-0.91) and western (OR 0.72, 95% CI 0.60-0.86) departments of Guatemala. On the other hand, rainfall was positively associated only with influenza positivity in Guatemala’s central departments (OR 1.05, 95% CI 1.01-1.09) and in Panama Province of Panama (OR 1.10, 95% CI 1.05-1.14). Temperature, however, was only associated with influenza positivity in west-central El Salvador departments, with a 20% reduction in the odds of influenza observed with each degree Celsius increase in temperature (OR 0.80, 95% CI 0.70-0.91). We found that the best model for El Salvador’s central departments had meteorological covariates from the previous 1 week, whereas the other locations had meteorological covariates that were averaged over two or more weeks. The resulting polynomial function of the week number for each study location can be found in the Supporting Information (Text S1, Figure S1 and Figure S2).

The models were subsequently used to estimate influenza positive proportion during the first half of 2013 (January to July 2013) (Figure 2). The blue curves in Figure 2 are the prospectively estimated influenza activity in 2013 using actual meteorological data and regression models trained with influenza data from previous years. The estimated activity closely resembled the actual activity for 4 out of the 6 study areas: Guatemala’s central departments, El Salvador’s west-central departments, and the 2 Panama provinces. The root mean squared error (RMSE) between the observed and estimated outputs ranged between 0.06 and 0.13, and correlation coefficients between 0.02 and 0.90 (Table 2). Based on the correlation coefficients, the models performed better in El Salvador’s west-central departments and Panama provinces, than in Guatemala departments. For Guatemala’s central departments, although the correlation coefficient was low, the estimated influenza activity shown in Figure 2 was able to closely follow the actual activity.

In the second best models (with the second lowest AIC), we found that the significant associations between influenza positive proportion and meteorological variables remained the same, except for rainfall in central Guatemala departments (Table S1). Specific humidity was significantly associated with influenza positive proportion in all locations, with inverse relationship in Guatemala and proportional relationship in El
Salvador and Panama. Temperature was significant only in El Salvador, and rainfall in Panama Province. In Guatemala’s departments and in El Salvador’s San Miguel Department, the differences in the AIC values between the best and the second best models were very small (0.36, 0.48 and 0.98 for San Miguel Department, and Guatemala’s western and central departments respectively). Typically, as a rule-of-thumb, a difference less than 2 in AIC indicates that the two models are indistinguishable. In Panama Province, the difference in AIC value was 2.07. While larger differences in AIC were found in Panama’s Chiriquí Province (3.40) and El Salvador’s west-central departments (4.21).

We used the best model to calculate the change in the influenza positive proportion throughout the study period when the significant meteorological variables were increased, one at a time, by one standard deviation (Figure 3). Here, temperature was increased by 2.74°C, specific humidity by 2.61 g/kg, and rainfall by 6.48 mm/day. Overall, the change in the influenza positive proportion was relatively small, ranging from 0.001 to 0.4 (with mean change ranging from 0.03 to 0.2). The mean change in influenza positive proportion when specific humidity was increased by one standard deviation ranged from 0.04 to 0.19. Largest change in positive proportion was found in Panama’s Chiriquí Province, and smallest change in Guatemala’s central departments. In El Salvador’s west-central departments, increases in both temperature and specific humidity resulted in similar change in the influenza positive proportion (-0.01 to -0.14 for temperature, 0.01 to 0.06 for specific humidity). In Panama Province, a one standard deviation increase in specific humidity would result in a slightly higher change in influenza positive proportion as compared to change in rainfall. When either rainfall or specific humidity was increased by one standard deviation, we observed influenza positive proportion change of 0.003 to 0.23 for specific humidity, and 0.001 to 0.15 for rainfall.

From the deviance analysis for the meteorological covariates, we found that the model deviances increased the most (Figure 4) when specific humidity was removed from the models in 4 out of the 6 locations studied (Guatemala’s central and western departments, El Salvador’s San Miguel Department and Panama’s Chiriquí Province). These results
indicated that among the meteorological covariates, specific humidity had the highest contribution to the models (4.66% in Guatemala’s western provinces, 2.56% in Guatemala’s central provinces, 4.77% in El Salvador’s San Miguel Department, and 6.95% in Panama’s Chiriquí Province). In El Salvador’s west-central provinces, both temperature and specific humidity had similar contribution (temperature 3.11%, specific humidity 2.95%). In Panama Province, among the meteorological variables, rainfall had the highest contribution to the model (6.05%) followed by specific humidity (1.81%).

**Discussion**

In this study, we evaluated the association between influenza activity – as measured by the proportion of respiratory samples tested positive for influenza (influenza positive proportion) – and meteorological variables in 6 study locations consisting of 11 departments or provinces in 3 Central American countries. After adjusting for previous weeks’ influenza activity and other respiratory viruses’ activities (RSV, parainfluenza viruses and adenoviruses), we found that specific humidity was significantly associated with influenza activity in all three countries, with proportional relationship in El Salvador and Panama, and inverse relationship in Guatemala. Temperature was found to be significantly and inversely associated with influenza activity in El Salvador’s west-central departments. Rainfall was proportionally associated with influenza in Guatemala’s central departments and Panama’s Panama Province. Among the meteorological covariates, specific humidity had the highest contribution to the model in 4 out of the 6 locations studied. Our results emphasized the association between influenza positive proportions and specific humidity across tropical Central America.

Our finding on the association between influenza activity and specific humidity in Guatemala supports results from experimental studies which demonstrate that low humidity is linked to more efficient aerosol-borne transmission [8] and better virus
survival [13]. This association had been largely demonstrated in the temperate regions [3,15,16], and in a few subtropical countries, such as Taiwan [46] and Hong Kong [35]. Although these 3 countries lie in the same tropical region in Central America and Guatemala is located next to El Salvador, most Guatemala’s cities are situated in highlands and have more temperate climate. Among all the study areas, Guatemala’s departments are cooler, with a minimum temperature of 8°C and maximum temperature reaching 29°C. Under such conditions, one could expect that aerosol-borne transmission would possibly become more efficient as humidity decreases [8].

In contrast to findings from temperate regions [15] and our result in Guatemala, our analyses of El Salvador and Panama data suggest that there was a significant association between increasing humidity and influenza transmission at those locations. Situated on highlands, the Guatemala departments have a cooler and less humid climate than the study locations in El Salvador and Panama. Our findings in El Salvador and Panama are different from influenza studies in the temperate regions where influenza was inversely associated with specific humidity [15]. However, our results are consistent with studies of other tropical countries. For example, multivariate analysis from Indian data showed a positive correlation between relative humidity and influenza positive isolates. Similarly, in Dakar, Senegal, influenza activity peaked during periods when humidity, rainfall and temperature were high [47,48]. A time series study on influenza A incidence in subtropical Hong Kong also showed a positive association between humidity and influenza transmission [49]. Furthermore, a recent study indicated that in locations with high specific humidity and temperature, influenza epidemics were characterized by months with highest humidity and rainfall [50]. The positive association between humidity and influenza activity may be indirect, similar to the crowding effect of rainfall that contributes to increased influenza activity. In modern societies, indoor public places may provide opportunities for crowding when it rains or humidity is high, and thus may enhance contact, aerosol and droplet transmission.

Our study indicated that influenza positive proportion was associated with rainfall only in Guatemala’s central departments and in Panama Province. However, in the second best
model for Guatemala’s central departments (with an AIC indistinguishable from the best model), rainfall was not a significant variable although specific humidity remained significant. This result implied that rainfall may not have as strong association with influenza activity in central Guatemala departments. Rainfall is often associated with influenza activity in the tropical countries, such as Philippines, western part of India [18] and French Guiana [51]. As previously mentioned, the association between rainfall and influenza activity is likely to be indirect. Rainfall may lead to indoor crowding and consequently increase the probability for contact and other modes of transmission. A global study on environmental predictors and influenza epidemics found that rainfall was the best predictor for influenza peaks for locations between 12.5°N–12.5°S [50]. Part of our result supported this finding as Panama Province is located approximately between 8°N–9.5°N, while Guatemala and El Salvador lie between 13°N–18°N. In addition, the deviance analysis indicated that rainfall had highest contribution to the model in Panama Province as compared to the other two meteorological covariates. However, we did not find significant association between influenza positive proportion and rainfall in Panama’s Chiriquí Province, which is also located between 8°N–9.5°N.

In El Salvador’s west-central departments, we found that influenza positive proportion was also significantly associated with temperature in addition to specific humidity. The inverse association with temperature is similar to what was found in the temperate regions and in an animal study [8]. However, temperature in El Salvador does not go as low as in the temperate regions. At higher temperature, aerosol-borne transmission may not be as efficient [21]. Hence our finding of an inverse association between temperature and influenza activity in El Salvador may not indicate a direct causal relationship between cool temperature and influenza transmission. Temperature in El Salvador may be a proxy for other factors which may facilitate influenza transmission which remain unaccounted for in our regression models.

From the models’ deviance analysis, we calculated the relative contribution of the meteorological variables to the model. Our findings indicated that these variables could contribute at most 6.95% to the model (specific humidity in Panama’s Chiriquí Province).
Similarly, we found that when the meteorological variables were increased by one standard deviation, the influenza positive proportion changed, on average, by 0.2 at most. The small contribution of meteorological variables to influenza modeling was also demonstrated in another study [52], albeit with a different model structure. The study showed that absolute humidity accounted for approximately 3% of the influenza variance in the Netherlands, while most variations were explained by the depletion of susceptible population and between-season effects. In spite of the small contribution of meteorological variable to influenza activity, this and other studies [52,53] showed that meteorological variables helped forecasting influenza epidemics.

When the models were used to prospectively estimate influenza positive proportion in the first half of 2013, the models performed best in Panama provinces and in the west central El Salvador departments. However, the models performed poorly in the Guatemala departments and El Salvador’s San Miguel Department. The models’ poor performances in these locations may indicated the dynamics that were not accounted for in the models, such as circulating strains, herd immunity, and socioeconomic factors that are difficult to account for mathematically. It is interesting to note that in the locations where the models performed better (west-central El Salvador departments, Chiriquí Province and Panama Province), influenza activity showed a distinct peak each year, whereas in the other locations there were multiple peaks in a year. Another study [50] indicated that meteorological predictors performed especially poorly in estimating influenza peaks in the middle latitude locations (12.5°N/S to 25° N/S), where Guatemala and El Salvador lie.

There were several limitations to our study. The meteorological data used in this study were outdoor measurements, whereas people in modern society spend much of their time indoors. In these 3 countries, indoor space may also be air-conditioned. However, we could not account for the difference in time spent in air-conditioned environments, and other social and economic parameters which may have a role in affecting the association between influenza activity and meteorological factors. We could only infer associations, but not causality, between influenza activity and temperature, specific humidity and
rainfall. Consequently, the associations we found may act only as proxies for factors not considered in this study, as we have previously discussed in the case of El Salvador’s west-central departments. In the analysis, we did not account for the role of vaccination which may further confound the association between influenza and the meteorological parameters. During 2012, however, the Vaccine Effectiveness Network in Latin America (known as REVELAC-I by its acronym in Spanish) documented that influenza vaccine coverage was typically low among persons targeted for vaccination (21-41% depending on the target age group, unpublished data). Another limitation to this study was the use of convenience sampling, which may contribute to biased results and difficulties for generalization.

Lastly, we used influenza positive proportion as a proxy of influenza activity, although it was not a direct measure of influenza morbidity or mortality. As we have explained in the method section, considering the nascent and still evolving influenza surveillance systems in the 3 countries, there were scant data alternatives. Therefore, the influenza positive proportion was at the moment the most suitable measure to represent influenza activity. In addition, the positive proportion has been adequate to determine the timing of influenza activity in Central America in an operational setting (Azziz-Baumgartner, personal communication), and also in other studies [3,38–40]. By using the positive proportion, we assumed that the dynamics of influenza virus positive proportion followed the dynamics of influenza morbidity or mortality. This assumption had mostly been corroborated in the temperate and subtropical regions [54] [55]. The influenza positive proportion represented the relative dynamics of influenza activity. Therefore, results from our study cannot be used to interpret the absolute magnitude of influenza activity.

**Conclusion**

Our study suggested an association between influenza activity and specific humidity in the tropical Central American countries. Over Guatemala’s highlands, where the climate
was more subtropical than tropical, and where the mean annual temperature was the lowest compared to El Salvador and Panama, influenza activity increased with decreasing specific humidity. For El Salvador and Panama, which have a hotter and more humid climate than Guatemala, we found that influenza activity was associated with increased specific humidity. This opposite association with humidity in different climates was also discovered in other studies. It is suspected that higher humidity in the tropics may provide uncomfortable conditions for outdoor activities, promote indoor crowding, and increase contact and other modes of transmission. Lower temperature was only significantly associated with influenza activity in El Salvador’s west-central departments and more rainfall was associated with increased influenza activity in Panama Province. Such associations with temperature and rainfall were also discovered in other studies. Further studies may incorporate heat index to better understand how temperature and humidity may work together to affect influenza activity. Interpreting the exact mechanisms of the associations between influenza and meteorological parameters is necessarily complex, especially when imperfect surveillance data is paired with meteorological data of finite spatiotemporal resolution, and when socioeconomic data is minimally available. In spite of the limitations, we demonstrated the possibility of forecasting influenza activity using a trained regression model and expected meteorological conditions (from weather or climate forecast). Just like weather forecast, the accuracy of influenza forecast may vary. It is hoped that with further refinement and more suitable meteorological data, such methodology may provide a sufficiently accurate reference point for public health in preparing for and responding to influenza epidemics.

Acknowledgments

The authors thank the staff of the laboratory influenza of Ministry of Health of Guatemala, Panama and El Salvador; the environmental team of the Ministry of Environment of each country; the PAHO Influenza Group; and the CDC Influenza Division, including Nancy Cox, Joseph Bresee and Ann Moen. We also thank Luis Bonilla for compiling influenza data, Jason Lefler for processing satellite data and Nivaldo Linares-Perez.

The models were adjusted for: potentially confounding variables (RSV, parainfluenza and adeno viruses), previous weeks’ influenza positivity, seasonality and other possible nonlinear relationships (modeled as a polynomial function, up to degree of 3, of the week number).
Supporting Information

I. Meteorological Data

Precipitation measurements were obtained from the Tropical Rainfall Measuring Mission (TRMM) satellite via NASA Goddard’s Geospatial Interactive Online Visualization and analysis Infrastructure (GIOVANNI) system [1]. We used the daily TRMM3B42 (V7) data product, which was the TRMM-adjusted merged-infrared (IR) precipitation with root-mean-square precipitation error estimates. How precipitation was derived for this data product is beyond the scope of this study, therefore we refer the readers to [2] for details. The spatial resolution of TRMM 3B42 data was 0.25° x 0.25° (~25x25 km). For each pixel, we calculated the areas covered by the study region. If more than 10% of a pixel area was covered by the study region, then we include the data from the pixel. We then averaged the data across the selected pixels, followed by 7-day average. ArcGIS was used to calculate the pixel area covered by the study region.

We used the Global Land Data Assimilation System (GLDAS) dataset to obtain temperature and specific humidity [3]. This dataset had a spatial resolution of 0.25° x 0.25°, and we used the same approach as described for TRMM dataset to select the pixels to be included. Once spatial averaging was performed, we took the weekly average.

As we have previously mentioned, for each meteorological parameter we first took the spatial average to generate one daily time series for each meteorological parameter. We then took the temporal average to create a weekly time series for each meteorological parameter. This weekly time series were also lagged to create 1- to 4-week lag time series. In addition to creating 1-week time series, we also averaged the data over 2 to 4 previous. We created different temporal averages because it was unknown a priori which time lag or average was associated with influenza activity. Various temporal aggregates have been used in influenza studies in the literature, from 1-week average to 8 months average [4–7].
I. 1. **Humidity**

Several humidity measures have been used in influenza studies, including absolute, relative and specific humidity, as well as vapor pressure. In this study, we used specific humidity. Humidity in general is a measure of water content in the air. Briefly, absolute humidity (AH) is the mass of water vapor per unit volume of air; and specific humidity (SH) is the ratio between mass of water vapor and the mass of air (typically expressed in g/kg).

For both AH and SH, as the water vapor content in the air increases, their values also increase. Relative Humidity (RH), on the other hand, depends on temperature. It is a measure of the amount of water vapor in the air compared to the maximum amount of vapor that can exist in the air at its current temperature. Warm air holds more water vapor than cold air. Hence one AH (or SH) can correspond to more than one RH. Relative humidity is defined as the ratio of the partial pressure of water vapor (vapor pressure, \(E\)) to the saturated water vapor at the given temperature \(E_s\).

In summary, AH, SH and RH can be written as:

\[
SH = \frac{m_v}{m_v + m_a} \tag{1}
\]

\[
AH = \frac{m_v}{V} \tag{2}
\]

\[
RH = \frac{E}{E_s} \tag{3}
\]

Where,

- \(m_v\) is the mass of water vapor
- \(m_a\) is the mass of dry air
- \(V\) is the volume of air
- \(E\) is the partial pressure of water vapor
- \(E_s\) is the saturated partial pressure of water vapor

Note that \(E_s\) is the partial pressure at which the air can hold the maximum amount of moisture at a given temperature.
I. 2. **Satellite data validation**

Satellite data validation is beyond the scope of this study. NASA satellite measurements go through stringent calibration and validation processes to ensure satellite data products provide accurate representation of the geophysical parameters (temperature, humidity, radiance, etc.) Some typical calibration and validation efforts are described in calval.jpl.nasa.gov and lpvs.gsfc.nasa.gov.

For example, TRMM data is continuously validated against ground observations located in Darwin (Australia), Houston (Texas), Kwajalein (Republic of the Marshall Islands) and Melbourne (Florida) [8]. The algorithms used to derive the TRMM 3B42 products had been validated at global scale with aggregated gauge data, resulting in correlation coefficient between the two that ranged between 0.545 to 0.864 [9]. Several studies have indicated that the accuracy of TRMM 3B42 varied across regions [10].

It should be noted that satellite-derived measurements are different from ground station observations for the following reasons. Satellite sensors have finite field-of-views. The measurement taken by a satellite sensor represents the average value within a pixel (satellite instrument’s footprint). On the other hands, measurements from ground stations are generally point values. Therefore, satellite measurements are intrinsically different from ground station measurements.

II. **Methods**

Logistic regression was used to model the weekly proportion of influenza positive samples. For a site $k$ and week $t$, if $Y_{kt}$ denotes the number of samples tested positive for influenza out of $N_{kt}$ samples examined, then $Y_{kt}$ is a binomial random variable. That is, $Y_{kt}$ \~ Bin ($N_{kt}$, $p_{kt}$) where $p_{kt}$ is the proportion that are tested positive in site $k$ in week $t$. If we denote the logit of the influenza positive proportion as:

$$z_{kt} = \ln \left( \frac{p_{kt}}{1 - p_{kt}} \right)$$

the logistic regression is then:
\[ z_{kt} = \alpha + \sum_{j=1}^{3} \beta_{jk} x_{jkt} + \sum_{l=1}^{3} \gamma_{lk} v_{lkt} + \sum_{m=1}^{4} \lambda_{mk} \omega_{k(t-m)} + \sum_{n=1}^{3} \theta_{nk} w_{kt}^{n} \]  

(5)

Where,

- \( x_{jkt} \) Meteorological variable \( j \) in location \( k \) at week \( t \); \( j \in \{\text{temperature, specific humidity, rainfall}\} \)
- \( v_{lkt} \) Proportion of samples that are positive for virus \( l \) in location \( k \) at week \( t \); \( l \in \{\text{respiratory syncytial virus (RSV), Adeno virus, Parainfluenza virus}\} \)
- \( w_{kt}^{n} \) Week number (1 to 52) at location \( k \)
- \( \alpha \) Intercept
- \( \beta, \gamma, \lambda, \theta \) Regression coefficients

In using the logistic regression model described in equation (4-5), we assumed that the probability of a sample tested positive for influenza followed binomial distribution (i.e., success/failure, or, presence/absence of influenza virus in a sample). Given the meteorological condition in week \( t \), the odds for proportion (or probability) of samples that were tested positive would be higher if the meteorological condition was suitable for influenza transmission because more people would likely be infected.

We used R software [11] to perform logistic regression, and supplied both the numbers of specimens tested positive and negative for influenza in each week. This approach for formulating logistic regression is delineated in the textbook by Crawley [12]. Logistic regression can be extended to model population proportion (or probability), where each observation is a proportion based on binomial response variables rather than individual binary scores of 0 or 1.

We fitted the full model as described in equation (5) for each location. A backward selection was then applied to select the polynomial order (denoted as \( n \) in equation (5)) of the week number (\( w \)) and the dependent variable lags (denoted as \( m \) in equation (5)), resulting in a reduced model. The backward selection iteratively eliminates variable whose removal optimizes the model performance. We used Akaike’s Information Criterion (AIC) as a measure for the model performance, which was defined as:
\[ AIC_k = -2 \ln (L_k) + 2 \Phi_k \]  

(6)

Where for location \( k \), \( \Phi_k \) is the number of parameter (regression coefficients: intercept and a coefficient for each independent variable in Equation 5) and \( L_k \) is the likelihood function defined as:

\[
L_k(p_k; y_k) = \prod_{t} N_{kt}! \left( \frac{N_{kt}!}{y_{kt}!(N_{kt} - y_{kt})!} \right)^{(p_{kt})^{y_{kt}}(1 - p_{kt})^{N_{kt} - y_{kt}}} 
\]

(7)

\[
\ln(L_k(p_k; y_k)) = \sum_{t} \ln \left( \frac{N_{kt}!}{y_{kt}!(N_{kt} - y_{kt})!} \right) + y_{kt} \ln(p_{kt}) + (N_{kt} - y_{kt}) \ln(1 - p_{kt}) 
\]

(8)

\( p_{kt} \) is the proportion of samples that are tested positive for influenza in location \( k \) and time \( t \), \( N_{kt} \) is the number of samples and \( y_{kt} \) is the number of samples that are tested positive for influenza.

For each location, we tested the model (equation (5)) for the different meteorological lags and average period, resulting in 11 different models. That is, we first tested the model using meteorological variables \( (x_{jk}) \) with 1-week lag, subsequently applied backward variable selection and recorded the AIC values. We then repeated this process using meteorological variables with lag 2 to 4 weeks and meteorological variables that were averaged over 2 to 4 previous weeks. Out of these 11 models, we selected the model with the lowest AIC value as the best model for each location. Lower AIC indicates a better model.

For each model, the severity of collinearity between the meteorological variables was assessed by computing the Variance Inflation Factor (VIF), which is a factor of how much the coefficient’s standard error would increase if the said predictor were not correlated with the others. A value of 1 indicates that the predictor is orthogonal to the others, and common practice considers VIF of 5 or 10 suggests severe collinearity [13,14]. In this study we used VIF of 10 as our threshold. We also assessed the autocorrelation in each model using Autocorrelation function (ACF) and partial autocorrelation function (PACF).

We used the best model to assess how much influenza positive proportion changed when the significant meteorological variables were increased by one standard deviation. For example, we added 2.61g/kg to the observed specific humidity and
calculated the influenza positive proportion at each week, while holding the other variables at their observed values. If we denote the resulting influenza positive proportion as \( \hat{p}_{kt} \), and the value of influenza positive proportion when the specific humidity was at their observed value as \( \hat{p}_{kt0} \), then the change in positive proportion at time \( t \) will be:

\[
\Delta p_{kt} = \hat{p}_{kt} - \hat{p}_{kt0}
\]  

(9)

We calculated this change for all data points, \( t \), and presented them in a boxplot (Figure 3).

One way to measure the discrepancy between a model and the observed data is using deviance. Model deviance is defined as -2 times the difference in log likelihood of the current model and a saturated model (i.e. one that fits data perfectly) [12]. Smaller deviance indicates a better model fit, analogous to the sum of squared residuals in the ordinary regressions. In R the deviance formula for binomial family is the following [12]:

\[
d_k = 2 \sum_i y_{ki} \ln \left( \frac{p_{ki}}{\hat{p}_{ki}} \right) + (N_{ki} - y_{ki}) \ln \left( \frac{1 - p_{ki}}{1 - \hat{p}_{ki}} \right)
\]  

(10)

Where \( p_{ki} \) and \( \hat{p}_{ki} \) are the observed and predicted proportion of influenza positive, respectively; and \( N_{ki} \) is the number of sample.

In order to assess the contribution of each meteorological variable to the model we calculated the percent change in the model’s deviance when the said meteorological variable was removed from the model. Let the deviance of the best model in location \( k \) be \( d_{Bk} \). We then removed one meteorological variable from the best model, fitted the reduced model and calculated the deviance, \( d_{sk} \). The percent change in the deviance will be:

\[
\% \text{ change} = 100 \times \frac{d_{sk} - d_{Bk}}{d_{Bk}}
\]

The increase in the model deviance, when the said meteorological variable was removed, approximately represented the amount of variance for which this variable can account.

III. Additional Result – Polynomial Function of Week Number
The model used a 3\textsuperscript{rd}-order polynomial function of the week number ($w_{kt}$) (last term in Equation 5) to represent seasonal and other nonlinear factors not accounted for by the meteorological variables or the other independent variables in the model. Note that we applied a backward selection to the polynomial terms as well as the lagged dependent variable term. With the estimated regression parameter $\theta_{nk}$, the functions are bounded in all study locations and formed continuous, inverted U-shaped curves (Figure S1) except in Panama Province. For Panama Province, the function started with higher values at the beginning to midyear and fell to lower value toward the end of the year. One possible explanation for the high value at the turn of the year is that the polynomial tried to accommodate secondary influenza outbreaks at the beginning of years 2008 and 2010 (training data) that were not accounted for by the other independent variables in the model. These secondary influenza outbreaks at the beginning of the year could be due to influenza introduced by tourists or returned travelers during the holidays and its subsequent limited propagation. Among these 3 countries, Panama had the highest number of international visitors annually (2010-2012 data) [15]. Furthermore, the tourist’s season that falls between mid-December to mid-April (dry season) coincides with influenza season in the Northern Hemisphere. Hence it is hypothesized that these small outbreaks at the beginning of the year were the limited propagation due to imported influenza cases.

In order to test whether these secondary outbreaks in Panama Province at the beginning of the year caused the jump in the polynomial function, we carried out the analysis with these observed outbreaks set to zero (no influenza activity). The outbreaks were detected using a simple and commonly used approach, by comparing the influenza positivity rate with the annual mean or median value. With these secondary outbreaks excluded, we obtained a continuous, inverted U-shape polynomial for Panama Province (Figure S2) just like in other study locations. Using such setting, the relationships with meteorological variables remained similar to the one reported in the main text (Table 2) where influenza was proportionally associated with both specific humidity (OR = 1.370 (1.003, 1.883)) and rainfall (OR = 1.092 (1.044, 1.141)), and a non-significant relationship with temperature. This test is only a simplified approach to support our
postulation for the underlying cause of the polynomial function curve. Further analysis and additional data would be needed to obtain the complete picture.
