(Received 8 April 2014; accepted 2 June 2014; published online 23 June 2014)

The refinement of the Robert-Bonamy formalism by considering the line coupling for linear molecules developed in our previous studies [Q. Ma, C. Boulet, and R. H. Tipping, J. Chem. Phys. 139, 034305 (2013); 140, 104304 (2014)] have been extended to asymmetric-top molecules. For H$_2$O immersed in N$_2$ bath, the line coupling selection rules applicable for the pure rotational band to determine whether two specified lines are coupled or not are established. Meanwhile, because the coupling strengths are determined by relative importance of off-diagonal matrix elements versus diagonal elements of the operator $-iS_1 - S_2$, quantitative tools are developed with which one is able to remove weakly coupled lines from consideration. By applying these tools, we have found that within reasonable tolerances, most of the H$_2$O lines in the pure rotational band are not coupled. This reflects the fact that differences of energy levels of the H$_2$O states are pretty large. But, there are several dozen strongly coupled lines and they can be categorized into different groups such that the line couplings occur only within the same groups. In practice, to identify those strongly coupled lines and to confine them into sub-linespaces are crucial steps in considering the line coupling. We have calculated half-widths and shifts for some groups, including the line coupling. Based on these calculations, one can conclude that for most of the H$_2$O lines, it is unnecessary to consider the line coupling. However, for several dozens of lines, effects on the calculated half-widths from the line coupling are small, but remain noticeable and reductions of calculated half-widths due to including the line coupling could reach to 5%. Meanwhile, effects on the calculated shifts are very significant and variations of calculated shifts could be as large as 25%. © 2014 AIP Publishing LLC. [http://dx.doi.org/10.1063/1.4883058]

I. INTRODUCTION

The modeling of the atmosphere from satellite-based, balloon-based, and Earth-based instruments requires spectroscopic parameters of atmospheric molecules, especially those of the water vapor molecule. It is obvious that the accuracy of the latter’s parameters is essential for users’ applications. In order to meet the accuracy requirement for the H$_2$O molecule, the H$_2$O spectroscopic databases have been updated many times.$^{1,2}$ In these updating processes, the theoretically calculated pressure broadened half-widths and induced shifts with the Robert-Bonamy (RB) formalism$^3$ have played an important role.

Mainly due to its practical importance, a lot of efforts have been made for years in order to improve the RB formalism.$^{4-7}$ Despite all these efforts, the RB formalism still contains several basic assumptions whose applicability was not thoroughly justified. A series of recent papers$^{8,9}$ have demonstrated that for simpler systems where results of the close coupling calculations$^{10}$ with sophisticated potentials are available, the RB formalism significantly overestimates the half-widths.

Recently, by scrutinizing one of the main approximations (i.e., the isolated line approximation) in the RB formalism, we have found that this approximation has been applied twice by these authors in developing their formalism.$^{11,12}$ First, in calculating the resolvent operator $1/(\omega - L_0 - iW)$, they have only considered the diagonal matrix elements of the relaxation operator $W$. This implies that they have neglected a required basis change within the linespace. Due to this simplification, effects from the line mixing are ignored. Second, when they applied the linked cluster theorem to remove the cutoff, they have assumed matrix elements of the operator of $\exp(-iS_1 - S_2)$ can be replaced by the exponential of the matrix elements of the operator $-iS_1 - S_2$. The latter means that they have neglected other required basis change at this stage as well. (We note that in order to unambiguously represent what happens in the second simplification procedure, we have proposed in Refs. 11 and 12 to name the second basis change and its consequences as the line coupling. Readers must be careful to distinguish the difference between the line coupling and the line mixing to avoid confusion.) With this replacement, effects from the line coupling are also ignored. We have found that the criterion of the second assumption is so stringent, that for many molecular systems of interest in atmospheric applications, it cannot be satisfied. As a result, significant effects from the line coupling are completely ignored in applying this approximation. In order to remedy this
problem, we have developed a new method to evaluate the matrix elements of the exponential of the operator and have refined the RB formalism such that the line coupling can be well taken into account. In our previous works, we have applied this method to simple linear molecular systems: Raman $Q$ lines of the auto-perturbed $N_2$ molecule and infrared $P$ and $R$ lines of $C_2H_2$ immersed in $N_2$. In comparison with calculated half-widths derived from the RB formalism, new calculated values for these lines are significantly reduced and become closer to the measurements.

Our main goal now is to improve the accuracy of calculated half-widths and shifts for the water vapor molecule. Because $H_2O$ is an asymmetric-top molecule and it has a much more complicated structure than linear molecules, we study the line coupling for $H_2O$ lines immersed in $N_2$ and consider the line coupling applicable for asymmetric-top molecules such as $H_2O$ is presented. In this frame of the formalism with the line coupling, we have developed a new method to evaluate the matrix elements for both the operator of $\hat{S}$ and $\hat{S}^2$ are presented. For this group and other groups consisting of strongly coupled lines. After identifying groups consisting of strongly coupled lines, we present discussions of the main topics are derivations of expressions for the half-widths and shifts for the water vapor molecule. Besides, because spectra of asymmetric-top molecules are more significant than those of linear molecules and consequently we could not draw quantitative conclusions about these effects. In the present study, by including all the imaginary parts in calculations, we have calculated the induced shifts of $H_2O$ lines with the line coupling. It turns out that effects on the shifts are more significant than on the half-widths.

The paper is arranged as follows. In Sec. II, the main frame of the formalism with the line coupling applicable for asymmetric-top molecules such as $H_2O$ is presented. In this section, the main topics are derivations of expressions for the off-diagonal matrix elements of $S_{2,middle}$. In terms of the two-dimensional (2D) Fourier transforms and discussions of the latter's profiles. Besides, because spectra of asymmetric-top molecules are more complicated than that of linear molecules and, consequently, to determine whether two lines of interest are coupled through the line coupling or not becomes a challenge. By considering symmetry properties of the $D$ matrices appearing in the expressions for $S_{2,middle}$ and analyzing the profiles of the main 2D Fourier transforms introduced, the coupling selection rules are established with which one is able to identify groups consisting of strongly coupled lines. After developing all necessary tools, in Sec. III we present numerical calculations of the half-widths and shifts for $H_2O$ lines in the pure rotational band broadened by $N_2$. By selecting one group consisting of strongly coupled 5 lines, detailed analyses of the matrix elements for both the operator of $-S_2$ and the operator of $\exp(-S_2)$ are presented. For this group and other eight sample groups, calculated half-widths and shifts with the line coupling are presented together with that obtained without the line coupling. In Sec. IV, we present discussions and conclusions.

II. THEORY

A. Diagonal matrix elements of the $S_2$ terms in the coordinate representation

With the RB formalism and other line shape theories, people usually only consider the Liouville scattering $\tilde{S}$ operator up to its second-order expansions consisting of two terms $S_1$ and $S_2$. As expected, evaluated $S_2$ is more difficult than $S_1$ and this is the main subject to investigate effects from the line coupling.

In our previous studies, we have presented general expressions for the matrix elements of $S_{2,outer,i}$, $S_{2,outer,f}$, $S_{2,middle}$ in the coordinate representation. These expressions are also applicable for more complicated molecules, but will not be presented here. In addition, the diagonal property of $S_{2,outer,i}$ and $S_{2,outer,f}$ within the same bands is also valid for asymmetric-top molecules. Meanwhile, the $S_{2,middle}$ term remains as an off-diagonal matrix. For asymmetric-top molecules immersed in a linear molecule bath, the explicit expressions for the diagonal matrix elements of $S_{2,outer,i}$, $S_{2,outer,f}$, and $S_{2,middle}$ have been derived in a previous work. Here, we briefly outline some derivation procedures.

For a system consisting of one asymmetric-top and one linear molecule, the potential models are usually given in terms of a spherical tensor expansion as:

$$V(\tilde{R}(t)) = \sum_{L_1,K_1,L_2} U(L_1L_2L; K_1; R(t)) \times \sum_{m,m',m''} C(L_1L_2L, m_1m_2m_3) L_{m_1L_2}^{m_3}(\Omega_a) \times L_{m_2L_2}^{m_3}(\Omega_b) Y_m^*(\omega(t)).$$

(1)

By introducing 2D correlation functions $G_{L_1,K_1',L_2}(t,t')$ defined as

$$G_{L_1,K_1',L_2}(t,t') \equiv \frac{(-1)^{K_1'+K_1}}{4\pi \hbar^2 (2L_1+1)^2 (2L_2+1)^2} \sum_L (-1)^{L_1+L_2+L} \times \sum_{L_1,L_2,L_3} \sum_{m,m'} U(L_1L_2L; K_1; R(t)) U(L_1L_2L; K_1'; R(t')) P_L(\cos \Theta_{t,t'})$$

(2)

and by changing their variables $t$ and $t'$ to new variables of $\tau \equiv t - t'$ and $\tau' \equiv \frac{1}{2} (t + t')$ (i.e., $t = t' + \frac{1}{2} \tau$ and $t' = t' - \frac{1}{2} \tau$ reversely), one obtains 2D symmetric correlation functions $G_{L_1,K_1,K_2}(\tau, \tau')$ defined by

$$G_{L_1,K_1,K_2}(\tau, \tau') = G_{L_1,K_1',L_2}(\tau' + \frac{\tau}{2}, \tau' - \frac{\tau}{2}).$$

(3)

The great advantages of these new functions result from their symmetry properties. In contrast with the original $G_{L_1,K_1,K_2}(\tau, \tau')$, the new $G_{L_1,K_1,K_2}(\tau, \tau')$ are even functions over the variables $\tau$ and $\tau'$. Then, by carrying out an integration of them from $-\infty$ to $\infty$, one obtains one-dimensional correlation functions,

$$G_{L_1,K_1,L_2}(\tau) = \int_{-\infty}^{\infty} dt' G_{L_1,K_1',L_2}(\tau, t').$$

(4)

Finally, in terms of $F_{L_1,K_1,K_2}(\omega)$, the Fourier transforms of these one-dimensional correlation functions, one is able to obtain explicit expressions for diagonal matrix elements of $ReS_{2,outer,i}$, $ReS_{2,outer,f}$, $S_{2,middle}$ which is real. Because $G_{L_1,K_1,K_2}(\tau)$ are even, $F_{L_1,K_1,K_2}(\omega)$ are real. With respect to $ImS_{2,outer,i}$ and $ImS_{2,outer,f}$, their expressions are given in terms of the Hilbert transforms of $F_{L_1,K_1,K_2}(\omega)$. Alterna-
Fourier transforms. With the fast Fourier transforms (FFT), the transforms are converted into their corresponding discrete presentation one can easily and accurately evaluate these correlation functions whose numbers are well limited. Meanwhile, based on the sampling theory, the continuous Fourier transforms are converted into their corresponding discrete Fourier transforms. With the fast Fourier transforms (FFT), the latter can be easily obtained. These very effective methods have been used in calculating $N_2$ broadened half-widths and induced shifts of $H_2O$ lines based on sophisticated potential models and the "exact" trajectory model in our previous works.\textsuperscript{13,14}

B. Off-diagonal matrix elements of the $S_{2,middle}$ term

For systems consisting of one asymmetric-top and one linear molecule, one needs to derive new expressions for the off-diagonal matrix elements of $S_{2,middle}$. In Appendix, we present main steps in deriving expressions for the off-diagonal matrix elements of $S_{2,middle}$. The derivations yield a primitive expression given by Eq. (A8) that serves as the starting point here. It turns out that the technique used to introduce the 2D correlation functions and their symmetric partners is also helpful here. However, due to interweaving variations of the variables $t$ and $t'$, one has to replace $(2L+1)P_L(\cos \Theta_{ij})/4\pi$ in Eq. (2) by their original expression of $\sum_{\ell M} Y^*_{LM} (\Theta_{ij}, \phi_{ij}(t)) Y_{LM} (\Theta_{ij}, \phi_{ij}(t'))$. In other words, one prefers to rewrite the 2D correlation functions $G_{L_1, K'_1 L_2}(t, t')$ as

$$
G_{L_1, K'_1 L_2}(t, t') = \frac{(-1)^{K'_1+K'_2}}{\hbar^2 (2L_1 + 1)(2L_2 + 1)} \sum_{LM} (-1)^{L_1+L_2+L} \times U(L_1, L_2 L; K_1; R(t)) U(L_1, L_2 L; K'_1; R(t')) Y^*_{LM} (\Theta_{ij}(t), \phi_{ij}(t)) Y_{LM} (\Theta_{ij}(t'), \phi_{ij}(t')).
$$

(5)

Then, in terms of these 2D correlation functions, the expression given by (A8) can be concisely expressed as

$$
S_{2,middle}^{i j, ij}(r_i) = (-1)^{j_i+j'_i} \sqrt{(2j'_i + 1)(2j'_i + 1)} \times \sum_{L_1, K'_1, L_2} (-1)^{j_i+j'_i+L_1} W(j'_i, j'_i, j_f, j_f, J L_1) D(v_i, j'_i, v_i, j_i; L_1 K'_1) D(v_f, j_f, v_f, j'_f; L'_1 K'_1)
$$

$$
\times \sum_{ij_1} (2j_1 + 1)(2j'_1 + 1) \rho_2 C^2 (\tau_{ij_1}^2, L_2, 000)
$$

$$
\times \int_{-\infty}^{\infty} dt \int_{-\infty}^{\infty} dt' e^{i(\omega_{ij} + \omega_{ij'} \tau)} e^{i(\omega_{ij'} + \omega_{ij} \tau')} G_{L_1, K'_1, L_2}(t, t').
$$

(6)

Furthermore, in order to exploit the advantages of the 2D symmetric correlation functions defined by Eq. (3), the integrations over $t$ and $t'$ in Eq. (6) can be expressed as

$$
\int_{-\infty}^{\infty} dt \int_{-\infty}^{\infty} dt' e^{i(\omega_{ij} + \omega_{ij'} \tau)} e^{i(\omega_{ij'} + \omega_{ij} \tau')} G_{L_1, K'_1, L_2}(t, t')
$$

$$
= \int_{-\infty}^{\infty} d\tau \int_{-\infty}^{\infty} d\tau' e^{i(\omega_{ij} + \omega_{ij'} \tau) + i(\omega_{ij'} + \omega_{ij} \tau')} \tau' G_{L_1, K'_1, L_2}(\tau, \tau').
$$

(7)

Except for necessary modifications resulting from considering asymmetric-top molecules, this expression is very similar to that obtained in our previous study for infrared $P$ and $R$ lines of linear molecules because the line coupling could also occur between lines in different branches. As a result, after making the modifications, all the procedures, including the introduction of the 2D Fourier transforms, developed previously in evaluating the off-diagonal matrix elements of $S_{2,middle}$ for linear molecules are also applicable for asymmetric-top molecules. Here, we only present the final expression for the off-diagonal matrix elements of $S_{2,middle}$ as.
The expression given by Eq. (8) is used to carry out numerical linear molecule bath. This process, one needs to introduce two kinds of cut-offs. Usually, when one can evaluate their corresponding 2D Fourier transforms, in resonance functions, and we follow the potential model used here, one can determine r_c,min, the minimum of the closest distance, for the “exact” trajectory model at T = 296 K is 3.5224 Å. In Figs. 1 and 2, we present the three-dimensional plot and the contour plot. These two figures demonstrate that F_{1000}(k, k') has four peaks whose heights are located at (4, 0), (−4, 0), (0, 10), and (0, −10) in the k and k’ coordinates. In addition, their slopes along the k axis are deeper than their slopes along the k’ axis. Roughly speaking, its magnitudes become negligible beyond the region of |k| ≤ 12 and |k’| ≤ 20. For r_c = 3.7 and T = 296 K, the value converts from ω (in cm⁻¹) to k (dimensionless) are k ≈ 0.092 × ω. As a result, the above region can be also described as |ω| ≤ 130 cm⁻¹ and |ω’| ≤ 217 cm⁻¹.

Similarly, we present the three-dimensional plot and the contour plot of F_{1002}(k, k’) at 3.7 Å in Figs. 3 and 4. As shown in the figures, it contains two peaks narrowly located at (0.75, 0) and (−0.75, 0) and its magnitudes are roughly limited in the region of |k| ≤ 4 and |k’| ≤ 3 (i.e., |ω| ≤ 43 cm⁻¹ and |ω’| ≤ 33 cm⁻¹). In comparison with F_{1000}(k, k’), it is obvious that the magnitudes of F_{1002}(k, k’) are significant smaller and are confined in the narrower region. Therefore, one can conclude

\[
S_{2,middle}^{L_1,L_2}(r_c) = 2\pi (-1)^{j_j + j_f} \sqrt{(2j_j' + 1)(2j_f' + 1)(2j_j + 1)(2j_f + 1)} \times \sum_{L_1,J_1,K_1,L_2,J_2} (-1)^{1+J+L_1} W(j_j'j_j, j_fj_f, J_1L_1) D(v_j'j_j, v_j, j_j; L_1 K_1) D(v_fj_f, v_fj_f, j_fj_f; L_1 K_1') \times \sum_{i,j} (2i_2' + 1)(2i_j' + 1) \rho_{ij} C^2(i_2'j_2L_2, 000) \bar{F}_{L_1,K_1,L_2} \left( \frac{\omega_{ij} + \omega_{j'}f_f}{2} + \omega_{ij}, \omega_{j'}f_f - \omega_{ff} \right),
\]

where \( \bar{F}_{L_1,K_1,L_2}(\omega, \omega') \) are the 2D Fourier transforms of \( \bar{G}_{L_1,K_1,L_2}(\tau, \tau') \) defined by

\[
\bar{F}_{L_1,K_1,L_2}(\omega, \omega') = \frac{1}{2\pi} \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} d\tau d\tau' e^{i\omega\tau} e^{i\omega'\tau'} \bar{G}_{L_1,K_1,L_2}(\tau, \tau').
\]

The expression given by Eq. (8) is used to carry out numerical calculations for asymmetric-top molecules immersed in the linear molecule bath.

C. Sample profiles of the 2D symmetric correlation functions and their 2D Fourier transforms

In the present study, we consider the line coupling within the pure rotational band of the H_2O molecule immersed in N_2 bath. We adopt the potential model by Gamache and Laraia used in their calculations of the half-widths and shifts for the HITRAN database. This is a typical complicated model containing a short-range interaction modeled by the site-site model.

With the RB formalism, the site-site model has to be transformed into its spherical expansion form first. During this process, one needs to introduce two kinds of cut-offs. The first is a cut-off to set the upper limits for tensor ranks L_1 and L_2. The second is a cut-off to limit expansion terms whose inverse powers of R(t) are not beyond certain numbers. In the present study, in order to evaluate the diagonal matrix elements of S_2, we have chosen 4 as the upper limits for L_1 and L_2 and selected 20th order cut-off to guarantee the convergence. With the current choice of 4, the number of the one-dimensional correlation functions is 132. Thanks to their symmetries, there are only 39 independent ones.

With respect to evaluations of the off-diagonal matrix elements of S_{2,middle}, the corresponding 2D correlation functions are required. Based on our previous works, we know that contributions to these off-diagonal matrix elements mainly come from nearly head-on collisions. This implies that among all the 2D correlation functions selected above, those having large magnitudes in regions with small closest distances are more important than others. Besides, due to symmetry restrictions, contributions from the 2D correlation functions with L_1 = 2 are either zero or completely canceled out in calculations. Based on these considerations, we have only considered those 2D correlations associated with three main independent ones labeled by (L_1, K_1, K’_2L_2) = (1000), (1002), and (3220, respectively. Among them, the 2D correlation functions of (1000) and (1002) are the two main contributors. It is worth mentioning that the two leading one-dimensional correlation functions with L_1 = 1 do not make any contributions to the diagonal matrix elements of S_{2,middle}.

Recall that all these 2D correlation functions are associated with specified collisional trajectories. Usually, the latter are labeled by the closest distance r_c (or the impact parameter b). As a result, they are also functions of r_c. With the coordinate representation, it is easy to calculate these 2D symmetric correlation functions. For shortening the paper, we do not present their profiles here. After these functions are available, one can evaluate their corresponding 2D Fourier transforms with the same tools developed previously. Usually, when people carry out practical calculations, they prefer to use dimensionless variables in resonance functions, and we follow their common custom here. Thus, for the 2D Fourier transforms, instead of ω and ω’, we use dimensionless variables k ≡ ωr_c/ν and k’ ≡ ω’r_c/ν, where ν is the mean velocity. We note that no explicit thermal average has been performed in the present study.

In order to show their profiles, we select the Fourier transforms of F_{1000}(k, k’) and F_{1002}(k, k’) at T = 296 K and choose two specified trajectories at r_c = 3.7 Å and 4.5 Å representing a nearly head-on collision and a collision between nearly head-on and glancing collisions. (Based on the potential model used here, one can determine r_c,min, the minimum of the closest distance, for the “exact” trajectory model at T = 296 K is 3.5224 Å.) In Figs. 1 and 2, we present the three-dimensional profile of F_{1000}(k, k’) at r_c = 3.7 Å and its contour plot. These two figures demonstrate that F_{1000}(k, k’) has four peaks whose heights are located at (4, 0), (−4, 0), (0, 10), and (0, −10) in the k and k’ coordinates. In addition, their slopes along the k axis are deeper than their slopes along the k’ axis. Roughly speaking, its magnitudes become negligible beyond the region of |k| ≤ 12 and |k’| ≤ 20. For r_c = 3.7 and T = 296 K, the value converts from ω (in cm⁻¹) to k (dimensionless) are k ≈ 0.092 × ω. As a result, the above region can be also described as |ω| ≤ 130 cm⁻¹ and |ω’| ≤ 217 cm⁻¹.
that for nearly head-on collisions, $F_{1000}(k, k')$ is more important than $F_{1002}(k, k')$.

Furthermore, in order to show their profiles for collisions between nearly head-on and glancing collisions, we present the three-dimensional plots for $F_{1000}(k, k')$ and $F_{1002}(k, k')$ at $r_c = 4.5 \text{ Å}$ and $T = 296$ K in Figs. 5 and 6. In comparison with $F_{1000}(k, k')$ at $r_c = 3.7 \text{ Å}$, the heights of $F_{1000}(k, k')$ at $r_c = 4.5 \text{ Å}$ are reduced by one order and its occupancy region is also reduced by five times. The latter is limited within $|k| \leq 3$ and $|k'| \leq 5$ or alternatively, within $|\omega| \leq 27 \text{ cm}^{-1}$ and $|\omega'| \leq 45 \text{ cm}^{-1}$ that results from the converting formula of $k \approx 0.112 \times \omega$ applicable at $r_c = 4.5 \text{ Å}$. This implies beyond nearly head-on collisions, $F_{1000}(k, k')$ fades away very quickly.

In contrast, the heights of $F_{1002}(k, k')$ are only slightly reduced and its occupancy region slightly increases (i.e., within $|k| \leq 4.5$ and $|k'| \leq 4$ or within $|\omega| \leq 40 \text{ cm}^{-1}$ and $|\omega'| \leq 36 \text{ cm}^{-1}$). This implies beyond nearly head-on collisions, $F_{1002}(k, k')$ declines slowly. In addition, in comparison with $F_{1000}(k, k')$, both its magnitudes and occupancy region of $F_{1002}(k, k')$ are larger. As a result, it becomes the major source responsible for the off-diagonal matrix elements.

D. Selection rules in determining coupled H$_2$O lines

For linear molecules, such as N$_2$ and C$_2$H$_2$, when one considers the line coupling, it is easy to determine their coupled lines.$^{11,12}$ Usually, numbers of their intense lines are very limited and there are no couplings between the lines with even and odd $j$ values. As a result, one only needs to divide the whole linespace into two sub-spaces constricted by even $j$ lines and odd $j$ lines, respectively. In addition, we know that for all the N$_2$ and C$_2$H$_2$ lines, the line coupling always happens and the effects are important. For asymmetric-top molecules, such as H$_2$O, to consider the line coupling has different features. First of all, to determine groups consisting of
In the present study, we choose the rule with \( L \) \( D \) \( = 0 \) as the selection rule because the symmetric correlation magnitudes of the off-diagonal matrix elements of \( S_{2,\text{middle}} \) between two lines of interest are mainly determined by two factors. One is the coupling strength factor defined by

\[
\sqrt{(2j_i^1 + 1)(2j_f^1 + 1)(2j_i^2 + 1)(2j_f^2 + 1)W(j_i^1, j_f^1, j_i^2, j_f^2, J, L, L_1)D(v_i^1, v_f^1, \tau_i^1, L_1, K_1)D(v_i^2, v_f^2, \tau_i^2, L_1, K'_1)}
\]

Another is \( \mathcal{F}_{L_1, K_1, K'_1} \equiv \frac{\omega_f - \omega_i}{\omega_f - \omega_i} \omega_{ij} + \omega_{fj} \). In cases that one of these factors is zero or negligible, one can ignore the line coupling between these two lines.

First of all, one can check whether the strength factor that contains a product of the two D matrices has non-zero values. For explanation convenience, we ignore the vibrational quantum numbers and rewrite the D matrix as \( D(j_{k_1}^1, k_2, k_3; L, K) \). There are rules to determine whether there is non-zero coupling between two states \( j_{k_1}^1, j_{k_2} \) and \( k_2, k_3 \) through the \( D(j_{k_1}^1, j_{k_2}; L, K) \) matrix. For example, the rule associated with \( L = 1 \) and \( K = 0 \) is similar to the selection rule of the \( \text{H}_2\text{O} \) transitions; \( \Delta j = j - j = 0, \pm 1, \pm 3, \cdots, \) and \( \Delta k_3 = k_3 - k_3 \equiv k_c - k_c = \pm 1, \pm 3, \cdots. \) In the present study, we choose the rule with \( L = 1 \) and \( K = 0 \) as the selection rule because the symmetric correlation functions with (1000) and (1002) are the dominant components responsible for the off-diagonal matrix elements. In addition, because magnitudes of \( D(j_{k_1}^1, j_{k_2}; L, K) \) decrease very quickly as \( \Delta k_3 \) and/or \( \Delta k_c \) increase, we add \( \Delta k_3 = \pm 1 \) and \( \Delta k_c = \pm 1 \) as an extra restriction. Then, by enforcing these restrictions on the D matrices of \( D(j_{k_1}^1, j_{k_2}; L, K_1) \) and \( D(j_{k_1}^1, j_{k_2}; L_1, K_1) \) associated with their initial and final states of two specified lines \( j_{k_1}^1, j_{k_2} \) and \( j_{k_1}^2, j_{k_2} \), one can determine whether they can be coupled or not. More specifically, both their initial and final angular moments must satisfy \( j_i^1 - j_i = 0, \pm 1 \) and \( j_f^1 - j_f = 0, \pm 1 \).

Meanwhile, their initial \( k_a \) and \( k_c \) quantum numbers must satisfy \( k_a - k_a = \pm 1 \) and \( k_c - k_c = \pm 1 \) and their final \( k_a \) and \( k_c \) quantum numbers must satisfy \( k_a - k_a = \pm 1 \) and \( k_c - k_c = \pm 1 \) as well. In terms of the indices \( j_i = k_a - k_c \) and \( j_f = k_a - k_c \), the \( \tau_f \) values of their initial states and also the \( \tau_f \) values of their final states for two coupled lines must have the same evenness or oddness. Here, it is worth mentioning that due to the dipole transition selection rule, for each of the transition lines of \( \text{H}_2\text{O} \), the \( \tau_1 \) and \( \tau_f \) values always have the same evenness and oddness. Finally, after enforcing this selection rule, there are no more restrictions required from \( W(j_i^1, j_f^1, j_i^2, j_f^2, J, L_1) \).

Armed with the selection rules, we have screened all pairs of \( \text{H}_2\text{O} \) lines in the pure rotational band listed in HITRAN 2008 and obtained a complete list of the coupled pairs. Most of lines have several coupled partners, but some lines are only coupled with one line. By tracing all connections through the line coupling, it turns out that the whole linespace is divided into two completely isolated sub-linespaces: one consists of lines with even \( \tau_1 \) (or \( \tau_f \)) values and another consists of odd \( \tau_1 \) (or \( \tau_f \)) values. Within a given sub-linespaces, all lines are connected. Their connections could be established directly through the line coupling between them or not directly through a series of couplings with other intermediate lines. Meanwhile, there are no connections existing between lines that belong to different sub-linespaces. Given the fact that there are 1639 \( \text{H}_2\text{O} \) lines listed and sizes of the two sub-linespaces are roughly the same, one has to take further steps to reduce the number of lines to be considered. One of them is to calculate the coupling strength factor first. Because the off-diagonal elements are simply proportional to its values, one can effectively rule out many weakly coupled pairs from considerations.

Then, by examining the second factor, one can develop a screening tool to easily and effectively identify strongly coupled lines. From profiles of \( \mathcal{F}_{1000} \) and \( \mathcal{F}_{1020} \) described in Sec. II C, one knows that non-negligible contributions to the off-diagonal elements of \( S_{2,\text{middle}} \) from these functions come only from the relatively narrow regions of \( k \) and \( k' \) (or alternatively, \( \omega \) and \( \omega' \)).
E. Diagonal matrix elements of the relaxation operator

It is well known that the relaxation operator $W$ contains all dynamical information of collisional processes. In the present study, we do not consider the whole matrix of the relaxation operator, rather focus attention on its diagonal matrix elements whose real and imaginary parts represent the pressure broadened half-widths and induced shifts, respectively. In terms of diagonal matrix elements of the exponential of the operator $-iS_1(r_c) - S_2(r_c)$, the expression for the diagonal elements of the relaxation operator $W$ is given by

$$W^i,j = \frac{n_b \bar{b}}{2\pi e} \int_{r_{c,\min}}^{+\infty} 2\pi \left( \frac{db}{dr_c} \right) \times dr_c \{ 1 - \ll i f | e^{-iS_1(r_c) - S_2(r_c)} | i f \gg \}, \quad (10)$$

where $n_b$ is the number density of the bath molecules. For H$_2$O lines in the pure rotational band, $S_i(r_c)$ is zero. Then, with Eq. (10), one can conclude that the most important step in calculating the half-width and shift is to evaluate the diagonal matrix elements of $\langle i f | \exp{-S_2(r_c)} | i f \rangle$. In fact, the essential difference between the usual method (without the line coupling) and the new method results from how to evaluate matrix elements for the exponential of a matrix. For the former, by assuming the isolated line approximation, one simply replaces $\langle i f | \exp{-S_2(r_c)} | i f \rangle$ by $\exp{-\langle i f | S_2(r_c) | i f \rangle}$. For the latter, by using tools to calculate the exponential of a matrix, one can correctly evaluates them without making this approximation.

III. SAMPLE CALCULATIONS FOR H$_2$O LINES BROADENED BY N$_2$

We present some tests of calculated half-widths and shifts of H$_2$O lines immersed in N$_2$ bath. By checking the coupling strength factor value and the two gap values for all coupled pairs in the pure rotational band, one can identify those strongly coupled pairs. The larger the strength factor is and the smaller the two gaps are, the stronger the coupling between them.

A. A sample group of coupled H$_2$O lines

For example, we have found that for the pair of 1569 ← 15510 and 15510 ← 15411, the strength factor is 1.0067 and the averaged energy gap and the frequency gap are 114.14 cm$^{-1}$ and 3.72 cm$^{-1}$, respectively. Although the energy gap is pretty large, it still remains in the region of efficiency of $F_{1002}(\omega, \omega')$ with small $r_c$ values. By comparing with other pairs, its three coupling parameters indicate the off-diagonal elements of $S_{2,\text{middle}}$ between these two lines could be pretty large. Besides, their half-widths are in the intermediate range. This implies that the diagonal matrix elements of $S_2$ are not too large. The latter is also important because what really matters for causing the line coupling is a comparison

| Coupled lines | Strength factor | $|\Delta E_1 + \Delta E_2|/2$ (cm$^{-1}$) | $|\Delta F|$ (cm$^{-1}$) |
|---------------|----------------|---------------------|----------------------|
| Lines 1 and 2 | -0.8302        | 176.06              | 39.69                |
| Lines 2 and 3 | -1.0243        | 134.25              | 43.93                |
| Lines 3 and 4 | 1.0667         | 114.14              | 3.72                 |
| Lines 4 and 5 | 0.8298         | 140.21              | 48.42                |
between the diagonal elements and the off-diagonal elements of the $S_2$ matrices. Based on these considerations, we expect that this pair could be strongly coupled.

After the core pair is selected, one needs to define a group consisting of the core pair and other coupled lines. By choosing the two cut-offs which are less stringent, other lines could be either coupled with $15_{50} \rightarrow 15_{510}$ or coupled with $15_{510} \rightarrow 15_{111}$. One can choose proper cut-offs such that at least one more coupled line is added. After completing this step, the group consists of the two core lines in the first-order hierarchy and new members in the second-order hierarchy. Then, for each of the new members, one finds their coupled lines in the third-order hierarchy and adds them in the group. One continues this procedure until there are no more lines allowed in the cut-offs. It is obvious that the size of groups depends on the cut-offs. The less stringent the cut-offs are, the larger the size is. In practice, one needs to adjust the two cut-offs which are less stringent, other lines could be included this way.

In Table I, we present the list of lines in this group including their frequencies and energy values of their initial states. Meanwhile, we also present the coupling parameters for all coupled pairs in Table II. With Table II, one can judge which of pairs have strong bonds and which have weak bonds. For example, the strongest bond occurs between Line 3 and Line 4 and the weakest two bonds occur between Line 1 and Line 2 and between Line 4 and Line 5. Numerical tests will verify this claim later.

In order to show matrices of $-S_2$ associated with nearly head-on collisions, we select the one at $r_c = 3.7\,\text{Å}$ and present it in Matrix 1. This is a complex asymmetric $5 \times 5$ matrix whose non-zero off-diagonal elements match the couplings between lines shown in Table II. The two largest off-diagonal elements (i.e., $1.1598 + i0$ and $1.3886 + i0$) are at the third row and the fourth column $(3,4)$ and at the fourth row and the third column $(4,3)$. This is well consistent with the largest strength factor (i.e., $1.0667$) and the two smallest gaps (i.e., $114.14\,\text{cm}^{-1}$ and $37.2\,\text{cm}^{-1}$) between Line 3 and Line 4. On the other hand, the smallest off-diagonal elements are at $(1,2)$ and $(2,1)$, and at $(4,5)$ and $(5,4)$. Given the fact that the coupling parameters between Line 1 and Line 2 (i.e., $-0.8302$, $176.06\,\text{cm}^{-1}$, and $39.69\,\text{cm}^{-1}$) and those between Line 4 and Line 5 (i.e., $0.8298$, $140.21\,\text{cm}^{-1}$, and $48.42\,\text{cm}^{-1}$) are less favorable to provide strong couplings, they are well expected. Finally, with respect to the diagonal elements, one can conclude that their imaginary parts are much smaller than their real parts.

### Matrix 1. The matrix of $-S_2$ at $r_c = 3.7\,\text{Å}$ for the group in Table I.

$$
\begin{bmatrix}
-1.2084 + i0.2168 & -0.1808 + i0 & 0 + i0 & 0 + i0 & 0 + i0 \\
-0.2133 + i0 & -1.9845 + i0.1555 & -0.5381 + i0 & 0 + i0 & 0 + i0 \\
0 + i0 & -0.5829 + i0 & -3.0569 - i0.7546 & 1.1598 + i0 & 0 + i0 \\
0 + i0 & 0 + i0 & 1.3886 + i0 & -2.9071 - i0.2495 & 0.3927 + i0 \\
0 + i0 & 0 + i0 & 0 + i0 & 0.4190 + i0 & -1.6804 + i0.1884
\end{bmatrix}
$$

Now, the task is to calculate the exponential of $-S_2$. In the present study, where both the calculated half-widths and shifts are considered, the matrices of $-S_2$ are complex. The method adopted consists of several steps. The first step is by diagonalizing the matrix $-S_2$, one finds its complex eigenvalues and complex right (or left) eigenvectors. From the former, one constructs a diagonal matrix $D$ and from the latter, one constructs a right eigenvector matrix $X_R$ whose columns represent the corresponding eigenvectors. Then, one finds the inverse matrix $X_R^{-1}$. After all these $D$, $X_R$, and $X_R^{-1}$ are available, the exponential of the matrix $-S_2$ is given by

$$
e^{-S_2} = X_R e^D X_R^{-1}.
$$

### Matrix 2. The matrix of $\exp(-S_2)$ at $r_c = 3.7\,\text{Å}$ for the group in Table I.

$$
\begin{bmatrix}
0.2962 + i0.0651 & -0.0385 - i0.0071 & 0.0071 - i0.0005 & 0.0022 - i0.0003 & 0.0002 - i0.0000 \\
-0.0454 - i0.0084 & 0.1566 + i0.0199 & -0.0553 + i0.0139 & -0.0254 + i0.0065 & -0.0041 + i0.0005 \\
0.0091 - i0.0007 & -0.0599 + i0.0150 & 0.0856 - i0.0626 & 0.0731 - i0.0382 & 0.0208 - i0.0048 \\
0.0033 - i0.0004 & -0.0330 + i0.0085 & 0.0875 - i0.0457 & 0.1064 - i0.0342 & 0.0513 - i0.0015 \\
0.0004 - i0.0000 & -0.0057 + i0.0008 & 0.0266 - i0.0062 & 0.0547 - i0.0016 & 0.1947 + i0.0355
\end{bmatrix}
$$
Matrix 3. The matrix of Re\{-S_2\} at r_c = 3.7 Å for group 1.

\[
\begin{array}{cccccc}
0.2917 + i0.0642 & 0 + i0 & 0 + i0 & 0 + i0 & 0 + i0 \\
0 + i0 & 0.1358 + i0.0213 & 0 + i0 & 0 + i0 & 0 + i0 \\
0 + i0 & 0 + i0 & 0.0343 - i0.0322 & 0 + i0 & 0 + i0 \\
0 + i0 & 0 + i0 & 0 + i0 & 0.0529 - i0.0135 & 0 + i0 \\
0 + i0 & 0 + i0 & 0 + i0 & 0 + i0 & 0.1830 + i0.0349
\end{array}
\]

In Matrix 2, we present the calculated matrix \(\exp(-S_2)\). As a reference, in Matrix 3, we present the matrix adopted in the RB formalism without considering the line coupling. It is a diagonal matrix whose diagonal elements equal to exponentials of the diagonal elements of \(-S_2\). By comparing Matrix 2 and Matrix 3, it is obvious that these two matrices are completely different.

Because the main subjects of the present study are calculated half-widths and shifts, one needs to focus attention on the diagonal elements of Matrix 2 and Matrix 3. By comparing them, one can conclude that the real parts of elements in Matrix 2, especially the third and fourth ones, are larger than their partners in Matrix 3. Given the fact that \(\{1 - \text{Re}\{\langle \langle \exp(-S_2) \rangle \rangle \}\}\) appear as a main part of the integrand in Eq. (10), one can expect that by considering the line coupling, we obtain two sets of functions for each of the factors and present their profiles in Figs. 7 and 8, respectively. As shown in Figs. 7 and 8, effects on their profiles from the line coupling are significant for Lines 3 and 4. More explicitly, magnitudes of the first factor with the line coupling are smaller than that without the line coupling. Meanwhile, magnitudes of the second factor with the line coupling are larger than that without the line coupling. As \(r_c\) increase, their gaps become narrower, and finally disappear. With respect to Line 2, the differences of the profiles are less noticeable. In summary, one should expect that for Line 3 and 4, it is necessary to consider the line coupling in evaluating the matrix of \(\exp(-S_2)\). In contrast, one does not need to consider the coupling for Line 2 at all.

Finally, after the diagonal elements \(\langle \langle \exp(-S_2(r_c)) \rangle \rangle\) as functions of \(r_c\) are available, one can easily calculate the half-widths and shifts for the five lines. In Table III, we list these calculated half-widths \(\gamma_{cp}\) (in cm\(^{-1}\) atm\(^{-1}\)) and shifts \(\delta_{cp}\) (in 10\(^{-3}\) cm\(^{-1}\) atm\(^{-1}\)) together with \(\gamma_{nocp}\) and \(\delta_{nocp}\) derived from the RB formalism without the line coupling. As a reference, relative differences \(\Delta\gamma/\gamma_{nocp}\) and \(\Delta\delta/\delta_{nocp}\) are also presented. With Table III, one can conclude that for Line 3 and Line 4, by considering the line coupling, the calculated half-widths are reduced by 4.5% and 5.1%, and meanwhile, their calculated shifts increase by 16.9% and 25.5%, respectively. These numbers demonstrate that effects on the calculated shifts are significantly larger than the calculated half-widths.

Finally, we would like to check whether the cut-offs used to define the group are suitable enough to yield converged results or not. One can easily check this by considering a sub-group only consisting of Line 3 and Line 4. Within the reduced 2 × 2 sub-linespace, we have repeated

**FIG. 7.** Profiles of \(1 - \text{Re}\{\langle \langle \exp(-S_2(r_c)) \rangle \rangle \}\) associated with the three H\(_2\)O lines are plotted. They are obtained from the modified RB formalism with and without the line coupling and are plotted by three solid and dotted-dashed curves, respectively. Lines 2, 3, and 4 (i.e., 1578 ← 1590, 1560 ← 1550, and 15510 ← 15411) are distinguished by black, red, and green colors.

**FIG. 8.** The same as Fig. 7 except for \(-\text{Im}\{\langle \langle \exp(-S_2(r_c)) \rangle \rangle \}\).
TABLE III. Calculated half-widths and shifts of lines in the group listed in Table I.

| Lines          | $\gamma_{\text{exp}}$ | $\gamma_{\text{cp}}$ | $|\Delta \gamma/\gamma_{\text{exp}}| \times 10^3$ | $\Delta \delta_{\text{exp}} \times 10^3$ | $\delta_{\text{exp}} \times 10^3$ | $|\Delta \delta_{\text{exp}}| \times 10^3$ |
|----------------|------------------------|------------------------|-----------------------------------------------|--------------------------------------|--------------------------------------|-----------------------------------------------|
| $15_{57} \leftrightarrow 15_{38}$ | 0.0460                 | 0.0458                 | 0.4                                           | -6.025                               | -6.071                               | 0.8                                           |
| $15_{78} \leftrightarrow 15_{60}$ | 0.0652                 | 0.0645                 | 0.9                                           | -2.262                               | -2.209                               | 2.4                                           |
| $15_{60} \leftrightarrow 15_{510}$ | 0.0807                 | 0.0770                 | 4.5                                           | 7.773                                | 9.084                                | 16.9                                          |
| $15_{510} \leftrightarrow 15_{311}$ | 0.0750                 | 0.0711                 | 5.1                                           | 3.464                                | 4.418                                | 25.5                                          |
| $15_{411} \leftrightarrow 15_{312}$ | 0.0553                 | 0.0550                 | 0.7                                           | -3.453                               | -3.458                               | 0.1                                           |

previous calculations, but we do not present the calculations here except for providing some final results. For Line 3, $\gamma_{\text{cp}} = 0.0775$ cm$^{-1}$ atm$^{-1}$, $|\Delta \gamma/\gamma_{\text{exp}}| = 4.0\%$, $\delta_{\text{cp}} = 8.889 \times 10^{-3}$ cm$^{-1}$ atm$^{-1}$, and $|\Delta \delta_{\text{exp}}| = 14.4\%$. For Line 4, $\gamma_{\text{cp}} = 0.0715$ cm$^{-1}$ atm$^{-1}$, $|\Delta \gamma/\gamma_{\text{exp}}| = 4.7\%$, $\delta_{\text{cp}} = 4.344 \times 10^{-3}$ cm$^{-1}$ atm$^{-1}$, and $|\Delta \delta_{\text{exp}}| = 25.4\%$. By comparing these numbers with those listed in Table IV, they are reasonably close. Therefore, one can conclude that for this group, the listed values in Table III are well converged and those obtained from the more reduced sub-linespace are also acceptable.

B. Results derived from other sample groups

We have considered dozens of groups containing strongly coupled lines. Based on our experience, strongly coupled lines, especially those with large $j$ values are more likely to have small frequency gaps and relatively large average energy gaps. For the groups with low $j$ values, their averaged energy gaps are smaller than that for the groups with high $j$ values. This is favorable in causing the line couplings. However, the former usually have larger half-widths and larger diagonal elements of $-S_2$ that work against the line couplings. The net effect results from the competition of these two factors.

Meanwhile, the sizes of the groups depend on the cut-offs used and also depend on their members’ $j$ values. If one applies the same cut-offs, groups consisting of lines with low $j$ values have more members than that with high $j$ values. This is well expected because energy level differences between different H$_2$O states with low $j$ values are smaller. However, as it has been explained above, for these groups one can apply more stringent cut-offs to limit their members. Finally, we have found that the groups to be considered could contain lines in different branches and lines could have three or more coupled partners. As a result, these groups have different sizes and have different coupling patterns. These features cause a difficulty of presentations to cover more sample groups with limited spaces.

Fortunately, as demonstrated in Sec. III A, by removing weakly coupled lines from the group, calculated results do not change too much. This convergence check enables one to simplify the presentation. In addition, because the potential model used here is not exact and there are other uncertainties existing in these semi-classical calculations, it is not our intention to provide accurate results and to cover all groups in the present study. Therefore, we prefer to use the simplest way to present results derived from these sample groups. More specifically, we have chosen eight typical groups with their $j$ values covering a wide range from $j = 3$ to $j = 18$ and have decided to present results derived from their sub-groups.

TABLE IV. Calculated half-widths and shifts of lines in other sample groups.

| Grp | Parameters | Lines | Freq. | $\gamma_{\text{exp}}$ | $\gamma_{\text{cp}}$ | $|\Delta \gamma/\gamma_{\text{exp}}| \times 10^3$ | $\delta_{\text{exp}} \times 10^3$ | $\delta_{\text{cp}} \times 10^3$ | $|\Delta \delta_{\text{exp}}| \times 10^3$ | $|\Delta \delta_{\text{exp}}| \times 10^3$ |
|-----|------------|-------|-------|-----------------------|-----------------------|-----------------------------------------------|--------------------------------------|--------------------------------------|-----------------------------------------------|-----------------------------------------------|

with 2 × 2 sub-spaces only consisting of their core pairs in Table IV where all the quantities listed are given in the same units as those in Tables II and III. In the second column of Table IV labeled as parameters, the coupling strength factor, the averaged energy, and the frequency gaps of the groups are listed. As shown in the table, all the frequency gaps of the eight groups are below 20 cm⁻¹, and meanwhile their averaged energy gaps, especially those with high j values, are much higher.

With the results listed in Table IV, one can conclude that effects on the calculated half-widths are small, but remain noticeable in the range from 1% to 4%. Meanwhile, variations of the calculated shifts are significant and some of them are above 15%. These conclusions are consistent with those in Sec. III A. We note that for the lines of 624 ← 615 in Group 4 and for the line of 725 ← 716 in Group 5, because their δnocp values are too small, values of [Δδ/Δnocp] lose their meaningfulness. In addition, we would like to note that by including more lines in these groups, the variations of [Δγ/γnocp] and [Δδ/δnocp] would increase, but the changes would not be too large.

Finally, it is worth mentioning that because the reductions and variations reported in Tables III and IV are derived from the potential model which is less accurate, once more accurate potentials become available and are used in calculations, these numbers could change. Therefore, it is better to treat these numbers as tentative.

IV. DISCUSSIONS AND CONCLUSIONS

Many papers have been devoted to the line mixing for molecular lines of interest in atmospheric applications. But, few of them explicitly carry out numerical calculations for the H2O lines. The paper by Lam in 1977 is one of the most important. Lam considered a linespace limited to the 11 H2O lines located in the microwave region. The non-diagonality of the Liouville scattering operator Ș within the linespace was taken into account, following an approximate procedure introduced by Dillon et al. Since the perturber was the N2 molecule, the potential was limited to the dipole-quadrupole interaction and the trajectories were assumed to be straight lines.

With the terminology adopted in the present study, the line mixing and the line coupling are two different concepts within the same linespaces, but they are closely related to each other. The former concerns the non-diagonality of the relaxation operator W appearing in the resolvent operator \(1/(\omega - L_0 - iW)\) and the latter concerns the non-diagonality of the operator \(-iS_1 - S_2\) appearing in the exponential operator of \(\exp(iS_1 - S_2)\). Besides, the selection rules to determine the line mixing and the line coupling are the same. In the RB formalism and other formalisms where the Liouville scattering operator Ș is given in terms of the cumulant expansions or other exponential forms, to consider the line coupling is a prior step for considering the line mixing. In fact, after calculations of the whole matrix elements of \(\exp(-iS_1 - S_2)\) are completed, one can easily derive the whole matrix elements of the relaxation operator W. Therefore, with the method described above, we can easily check Lam’s work.

In principle, as one considers the line coupling for lines located in the microwave region, one needs to take into account of both the positive-frequency lines and the negative-frequency lines. Indeed as is known from Ben-Reuven, positive and negative resonances are coupled by inelastic collisions. A careful analysis has shown that no efficient couplings exist between the 11 positive lines considered by Lam and their negative partners that corroborate his treatment.

In spite of his simplifying treatments of the potential and trajectory models, his four conclusions (see p. 374 of Ref. 18) are confirmed by the present work, regarding either the mixing selection rules or the weakness of the off-diagonal elements mixing some of these lines. However, by using our formalism and checking values of the line coupling parameters for those pairs considered by him, we have found that none of them are in favor of the line coupling. More specifically, among all the 11 lines, the strongest coupling happens between 414 ← 321 and 423 ← 530 and its three coupling parameters are -0.4786, 74.39 cm⁻¹, and 2.26 cm⁻¹. In addition, these lines have large half-width values. Indeed, we have found that reductions of the calculated half-widths for the two lines mentioned above are less than 0.5% and variations of the shifts are less than 3%. As a result, the group considered by him is not a candidate to have significant effects. His conclusions are correct, but the applicability is limited. One should not apply it everywhere without exception.

Because the main targets of the present work are calculated half-widths and shifts, we draw conclusions on these subjects. First of all, with respect to the half-width, one can conclude that for most of the H2O lines in the pure rotational band, effects from the line coupling are small or negligible. This implies that for most of the H2O lines, one does not need to consider the line coupling at all. However, the above claim does not apply for a certain number of lines, or more explicitly, for several dozens of lines. For the latter, reductions of their calculated half-widths due to the line coupling are noticeable and can reach above 5% or a little bit more.

Second, with respect to the calculated shift, the situation is quite different. In general, for most of the H2O lines in the pure rotational band, effects from the line coupling are small or negligible. This means again that one does not need to consider the line coupling for them. However, for several dozens of lines or a little more, effects from the line coupling are very significant and variations of calculated shifts can reach ±25% or even more. Fortunately, based on their coupling parameters and their j values, one can determine their identities.

In summary, our conclusions of the half-widths and shifts are different: the calculated shifts are more sensitive to the line coupling than the half-widths. It is well known that the imaginary parts of the diagonal elements of \(-S_2\) are almost one order smaller than the real parts. Thus, in comparison with the off-diagonal elements, the former are comparable or even less and the latter are much larger. As a result, with respect to the real off-diagonal elements, relative differences of the imaginary parts and of the real parts are completely different. It turns out that the real off-diagonal elements of \(-S_2\) not only affect the real parts of the exponentials \(\exp(-S_2)\), but also the imaginary parts. Meanwhile, in both cases, the
effects are more or less closely related to the relative differences mentioned above. Therefore, it is not surprising that the line coupling could cause larger effects on calculated shifts. Besides, values of shifts are much smaller than widths. In calculating the shift where the Hilbert transforms are involved and the latter are odd functions, there are a lot of cancellations happening and the final values result from small differences among large items involved. As a result, slight changes of values of these items could yield a large difference.

So far, we have only considered H2O lines in the pure rotational band. It is worthwhile to extend this study to other bands, especially the ν2 band. Indeed, we expect that for this band, effects from the line coupling may be at least as significant as those for the pure rotational band. Moreover, there was a paper by Brown et al.,21 where line mixing measurements for two pairs in the ν2 band were reported. One consists of two P branch lines (i.e., 101 ← 212 and 212 ← 303) and another consists of two R branch lines (i.e., 303 ← 212 and 212 ← 101). Based on the present work, one can easily verify that these authors have made good selections for their measurements because these doublets are strongly coupled. For the first pair, the three coupling parameters are −0.9705, 57.88 cm−1, and 1.24 cm−1. Meanwhile, for the second pair, the parameters are −0.9705, 55.27 cm−1, and 0.87 cm−1. (We note that because we have used the wavefunctions derived in the pure rotational band to calculate the coupling strength factors, their exact values may slightly differ from that provided above.) In general, their measured results for N2 broadened half-widths and shifts are consistent with our expectations. However, more quantitative comparisons require one to carry out numerical calculations.

Finally, our current formalism is applicable within the same band. For H2O lines belonging to different bands, the line coupling caused by intramolecular resonances (such as Coriolis, Fermi, Darling-Dennison, and more complex resonances) could also occur.22 In this case, besides the S2,middle term, both S2,outer,i and S2,outer,f can make contributions to the off-diagonal elements of S2. More work is required to extend to these complicated cases.

APPENDIX: DERIVATION OF EXPRESSIONS FOR THE OFF-DIAGONAL ELEMENTS OF S2,middle

As shown in our previous work, by applying the cumulant expansion on the Liouville scattering S operator and introducing basic vectors in the linespace defined by

\[ |i f, J M J⟩ = \sum_{m_i m_f} (-1)^{j_i m_i} C(j_i j_f J, m_i - m_f M_J) |i m_i f m_f⟩ \]

one is able to derive general expressions for the matrix elements of S2,outer,i, S2,outer,f, and S2,middle. Here, we show how to derive a more explicit expression for the off-diagonal matrix elements of S2,middle. The derivation starts from their general expression given by

\[ S_{2,middle}^{i,i'}f,f' = \frac{1}{\hbar^2} \int_{-\infty}^{\infty} dt \int_{-\infty}^{\infty} dt' \ll i' f', J M_J |(\mathcal{L}_i(t)\mathcal{L}_f(t))|i f, J M_J \gg_{middle} \]

\[ = -\frac{1}{\hbar^2(2J+1)} \int_{-\infty}^{\infty} dt \int_{-\infty}^{\infty} dt' \sum_{i_j m_2} \sum_{i' j m_2} \sum_{m} \rho_{i_2} e^{i(\alpha_1 + \alpha_2 + \beta_2)} e^{i(\alpha_f + \alpha_1 + \beta_1)} \times \int d\Omega_α \int d\Omega_β \langle f m_f j m_2 | β \rangle V_α(R(t)) β |i m_i i' m_2⟩. \]

(A2)

For the H2O molecule, wavefunctions of its rotational states are well known. With a simple notation, they are denoted by |i, τi, m_i⟩, where τi = k_αi - k_βi or simply by |i m_i⟩. By following the convention adopted by Zare,23 Bunker and Jenson,24 the H2O wavefunctions at specified orientation labeled by α can be expressed as

\[ ⟨α |i m_i⟩ = \sqrt{\frac{2J_i + 1}{8π^2}} \sum_k U_{k_α i}^{m_α - k} D_{m_i - k}^{m_β} (Ω_{αβ}). \]

(A3)

Meanwhile, for the bath molecule of N2, the expression for its wavefunctions is given by

\[ ⟨α |i z m_2⟩ = Y_{i z m_2} (Ω_{αβ}). \]

(A4)
With Eq. (1) and Eqs. (A3) and (A4), the integration over $\Omega_\alpha$ in Eq. (A2) can be expressed as

$$\int d\Omega_\alpha (i' m'_1 i'_2 m'_2 | \alpha) V_\alpha (R(t)) (\alpha | i m_1 i_2 m_2)$$

$$= \frac{\sqrt{(2 j'_1 + 1)(2 j'_2 + 1)}}{8 \pi^2} \sum_{k, L_1, L_2} U^*_{k, L_1 L_2} \sum_{n} \sum_{\mu_1 \mu_2 \mu_m} U(L_1 L_2; n; R(t)) C(L_1 L_2 L; \mu_1 \mu_2 m)$$

$$\times (-1)^{m - k} \left[ \int d\Omega_{ba} D^{j' \alpha}_{m, k} (\Omega_{ba}) D^{j'' \alpha}_{m, -k} (\Omega_{ba}) D^{L \alpha}_{\mu} (\Omega_{ba}) \right]$$

$$\times \left[ \int d\Omega_{ba} Y^{*}_{lm_2} (\Omega_{ba}) Y_{Lm_2} (\Omega_{ba}) \right] Y^*_{Lm_2} (\alpha_\beta (t)).$$

(A5)

After analytically carrying out the integrations over $\Omega_{a\alpha}$ and $\Omega_{ba}$, Eq. (A5) can be written as

$$\int d\Omega_\alpha (i' m'_1 i'_2 m'_2 | \alpha) V_\alpha (R(t)) (\alpha | i m_1 i_2 m_2)$$

$$= \sqrt{(2 j'_1 + 1)(2 j'_2 + 1)} \sum_{L_1, L_2} (-1)^{K_1} \prod (2 L_1 + 1)(2 L_2 + 1)$$

$$\times C(i'_2 i'_2 L_2, 000) U(L_1 L_2 L; K_1; R(t)) D(v'_j j'_L j'_2; L_1 K_1) \sum_{M_1 M_2 M} (-1)^{m_i + m_2}$$

$$\times C(L_1 L_2 L; M_1 M_2 M) C(j'_j j_1 L_1, m'_i - m_1 M_1) C(i'_2 i'_2 L_2, m'_2 - M_2 M_2) Y^*_{LM} (\alpha_\beta (t)).$$

(A6)

In the above expression, the D matrix is defined by

$$D(v'_j j'_L k K L; K L) = \sum_k (-1)^{i k} U^*_{i, L_k L} U_{k, L K} C(k' j') C(j' j L; k K - K).$$

(A7)

Similarly, one can obtain a similar expression for the integration over $\Omega_\beta$ in Eq. (A2). Then, with replacing the integrations over $\Omega_{a\alpha}$ and $\Omega_{ba}$ in Eq. (A2) by these two expressions and carrying out summations over all the independent magnetic quantum numbers except for M, one is able to rewrite Eq. (A2) as

$$S^{i j, i j}_{2, middle} (r_c) = (-1)^{k + \ell} \sqrt{(2 j'_1 + 1)(2 j'_2 + 1)} (2 j_f + 1)$$

$$\times \sum_{L_1, K_1 K_2 L_2} (-1)^{i + J + L_1} W(j'_j j'_L j'_2, J L_1) D(v' j' j'_L j'_2; L_1 K_1) D(v_j j_f j_f; L_1 K_1)$$

$$\times \sum_{i_2 j_2} (2 L_1 + 1)(2 L_2 + 1) \delta_{i_2 j_2} C^2(i'_2 i'_2 L_2, 000) \frac{(-1)^{K_1 + K_2}}{h^2(2 L_1 + 1)(2 L_2 + 1)^2}$$

$$\times \sum_{L} (-1)^{l + L_2 + L} \sum_{M} \int_{-\infty}^{\infty} dt \int_{-\infty}^{\infty} dt' e^{i \tau_1 + \alpha_1 \tau_2} e^{i \alpha_1 + \alpha_2 \tau_2} e^{i \alpha_1 + \alpha_2 \tau_2}$$

$$\times U(L_1 L_2 L; K_1; R(t)) U(L_1 L_2 L; K'_1; R(t')) Y^*_{LM} (\theta_\alpha (t), \phi_\alpha (t)) Y_{LM} (\theta_\beta (t'), \phi_\beta (t')).$$
