A Habitable Fluvio-Lacustrine Environment at Yellowknife Bay, Gale Crater, Mars

The Curiosity rover discovered fine-grained sedimentary rocks, which are inferred to represent an ancient lake and preserve evidence of an environment that would have been suited to support a martian biosphere founded on chemolithoautotrophy. This aqueous environment was characterized by neutral pH, low salinity, and variable redox states of both iron and sulfur species. Carbon, hydrogen, oxygen, sulfur, nitrogen, and phosphorus were measured directly as key biogenic elements; by inference, phosphorus is assumed to have been available. The environment probably had a minimum duration of hundreds to tens of thousands of years. These results highlight the biological viability of fluvial-lacustrine environments in the post-Noachian history of Mars.

The environmental history of early Mars is mostly written in stone. The first few billion years of Mars’ geologic history document surface environments considerably different than the surface today, prompting a succession of coordinated surface and orbiter missions over the past two decades aimed at ultimately determining if Mars ever had an early biosphere. Water is the essential ingredient for life as we understand it; therefore, past missions have sought environments in which water was abundant and possibly long-lived. However, to create an environment that could have been habitable by microorganisms, the presence of water alone is insufficient: A source of energy to fuel microbial metabolism is required, as are the elements carbon, hydrogen, sulfur, nitrogen, and phosphorus (and a host of others at trace levels). The Mars Science Laboratory (MSL) rover Curiosity was designed and built to search for these materials and, thus, potentially delineate one or more habitable environments at the Gale crater landing site. We show here that Gale crater once contained an ancient lake that would have been well suited to support a martian biosphere founded on chemolithoautotrophy.

Exploration for habitable environments is Curiosity’s core mission objective. Achieving this goal necessitates a challenging set of science measurements on just the right rocks to extend beyond the search for aqueous environments. To enhance the probability of mission success, we adopted an exploration strategy that included well-defined secondary objectives in addition to exploring Gale’s central mountain, Aeolis Mons (informally known as Mt. Sharp), the mission’s primary science target. The selection of the Gale crater field site, where Curiosity landed on 6 August 2012, 5:32 UTC, was based on the recognition that it retained records of diverse and ancient aqueous environments and thus enhanced the potential that one or more of those settings might have provided the combination of factors necessary to sustain a habitable environment (†). Another important factor included mapping the landing ellipse ahead of landing so that no matter where the rover touched down, our first drive would take us in the direction of a science target deemed to have the greatest value, as weighed against longer-term objectives and the risk of mobility failure.

Mapping and Geologic Framework for Exploration

Gale crater is 154 km in diameter with a central mountain of stratified rock. Gale straddles the crustal dichotomy boundary, a topographic demarcation between heavily cratered uplands and sparsely cratered lowlands. In the vicinity of Gale, the dichotomy boundary is crossed by numerous incised valley networks suggestive of surface aqueous flows that discharged to the north across the lowlands (‡). Gale’s stratigraphy, mineralogy, and landforms have been well studied from orbit (3–6). A broader context for understanding Mt. Sharp has been developed (7), along with Gale’s relevance to MSL’s goals (1, 8). The primary mission objective is to examine the lower foothills of Mt. Sharp (Fig. 1A), located outside of the landing ellipse, where hematic and hydrated clay- and sulfate-bearing strata were detected from orbit (5, 9) and are accessible by the rover (1).

The surface mission was planned in advance (1) to take into account the drive distance from anywhere in the landing ellipse up to and across the Mt. Sharp foothills, including time for sampling and analyses en route. The landing ellipse is located in the broad valley (Aeolis Palus) between the Gale crater rim and Mt. Sharp (Fig. 1A). Depending on where

Curiosity touched down, potential secondary science targets within the landing ellipse included the Peace Vallis alluvial (water-deposited) fan lobe; a high-thermal inertia terrain localized downslope from and adjacent to the fan; several fresh craters; and inverted stream channels. In the case of the current study, a secondary target near the landing site became a notable objective, with the decision (10) made after landing to drive in the opposite direction of the Mt. Sharp entry point to sample stratified rocks of relatively high thermal inertia exposed at Yellowknife Bay (11) (Figs. 1A and 2A).

Geologic mapping (12), building on earlier efforts (4), proved critically important to selecting the postlanding drive direction and science targets. This work provided the broader context in which to understand the strata drilled by Curiosity in Yellowknife Bay. The MSL team-generated map (Fig. 1B) reveals six units (13) that are distinguished based on variations in thermal inertia; textural attributes such as the presence of scarp and lineations consistent with bedding; surface roughness based on shadowing; apparent relative albedo; and patterns of albedo variation such as those indicating fractures, bedding, or mottling. These units include the Peace Vallis alluvial fan (AF); an immediately adjacent and downslope light-toned, bedded, fractured unit (BF); surfaces with relatively high crater densities (CS); tonally smooth but hummocky plains (HP); light-toned topographically variable or rugged terrain (RT); and light-toned
striated rocks (SR). By sol 440 (where 1 sol is a martian day), the RT and SR units had not been examined by Curiosity and are not discussed further. Both are considered as exposures of bedrock based on textures and higher thermal inertia values. The CS unit was inspected only from a distance during the traverses to and from Yellowknife Bay and probably reflects lateral equivalents of bedrock studied by Curiosity, discussed further below.

The HP unit is exposed in the vicinity of Bradbury Landing (14) and has lower values of thermal inertia. It is composed dominantly of loose materials, including clasts interpreted to be impact ejecta, but also displays erosional remnants of underlying bedrock. Analyzed clasts have basaltic, alkaline (K- and Na-rich) compositions (15), and some clasts and soils contain crystals of probable feldspar (16). Windows through this material in the vicinity of Bradbury Landing, including the excavation zones produced by Curiosity’s descent rockets, expose pebble conglomerate bedrock of fluvial (stream-related) origin (17).

The AF and BF units are important because of their intimate spatial association and possible relation to rocks exposed at Yellowknife Bay. The AF unit is defined by the Peace Vallis fan, which extends from the northwest rim of Gale crater (Fig. 1B); it may be the youngest component of a much more extensive alluvial plain that flanks the crater wall (4). The Peace Vallis fan probably formed by routing of eroded crater rim-derived rock fragments and any materials that accumulated there after crater formation, through Peace Vallis followed by downstream spreading and deceleration of flows and deposition of sediments in the downslope direction. The upslope part of the AF unit is marked by smooth mottled surfaces punctuated by slope-aligned linear ridges with a relief of 0.5 to 2.5 m interpreted as inverted stream channels. Downslope, this unit passes into the widespread BF unit that continues all the way to Yellowknife Bay, where it is coincident with the stratified bedrock exposed there and the terrain that marks the floor of the “bay” (18) itself. Although map relations suggest that the BF unit represents distal fan facies (rock types), these relations do not require that the Yellowknife Bay BF exposures be contemporaneous with the Peace Vallis lobe of the alluvial plain; they could represent an older component of the alluvial plain, separated from the youngest activity by an unconformity (see below). Nevertheless, the close spatial association implies a genetic link, with the BF unit having formed in a probably distal alluvial or even lacustrine (lake-related) setting, consistent with earlier mapping (4).

Geologic units in the interior of Gale crater display a range of relative ages and preserve a substantial record of geologic activity since the crater formed close to the Noachian–Early Hesperian boundary ~3.7 billion years ago (6). The oldest units are probably of Early Hesperian age and likely include the bulk of the alluvial plain that extends downslope of the crater rim. The Peace Vallis alluvial lobe (map unit AF) appears to represent the latest stage of transport and deposition on the alluvial plain. Our mapping shows that strata exposed at Yellowknife Bay are probably fan, distal fan, or downslope equivalents such as lacustrine deposits. Despite the ambiguity in the relative age of these strata, the fluvial-lacustrine depositional context remains intact, and this is what motivated the MSL Science Team to explore these rocks.

Stratigraphy and Sedimentology of Yellowknife Bay Rocks

Bradbury Landing occurs near the crest of a broad topographic high, several kilometers in width, informally called Bradbury Rise. To the north and east, the rise descends to rocks of the BF unit. After landing, the team-consensus decision was to traverse eastward and downhill to the HP-BF contact, as close as possible to the triple junction where the CS unit also intersects (Fig. 1B). Between Bradbury Landing and Yellowknife Bay, Curiosity crossed a straight-line distance of 445 m and descended 18 m in elevation. Most of this distance was spent traversing the clast-strewed HP unit, with its occasional outcrops of pebble conglomerate facies. Beginning at the Bathurst Inlet outcrop, a succession of strata was encountered with good exposure down to the floor of Yellowknife Bay (Fig. 2A). In ascending order, these strata are informally named the Sheepbed (~1.5 m thick), Gillespie Lake (~2.0 m thick), and Glenelg members (~1.7 m thick); the assemblage of members is known as the Yellowknife Bay formation, and the exposed section is ~5.2 m thick. (Fig. 3 and table S1). Strata are largely decimeter-scale in thickness and comprise a heterogeneous assemblage.
Exploring Martian Habitability

of mostly detrital sedimentary rocks of basaltic bulk composition. Breaks in outcrop continuity due to accumulated loose materials on the slope (Fig. 3) introduce a degree of uncertainty in understanding lateral extent of bedding; the lowest stratigraphic members (Sheepbed and Gillespie Lake) are best exposed around the perimeter of Yellowknife Bay (Fig. 2B). The Glenelg member contains a diverse suite of facies formed of beds with demonstrably less lateral continuity, although most beds can be traced for at least tens of meters.

The basal Sheepbed and Gillespie Lake members are characterized (19) by elemental compositions broadly consistent with a provenance that, on average, is similar to typical martian upper crust (20). In addition, these rocks carry the signal of higher thermal inertia as seen from orbit. Subtle geochemical variations within and between these units mostly reflect minor variations in provenance. A marked change in composition, best reflected by a sharp increase in $K_2O$ contents and $K_2O/Al_2O_3$ ratios (Fig. 4), takes place higher in the section in the Glenelg member (Bathurst Inlet outcrop), suggesting a fundamental change in the provenance to one dominated by more alkaline igneous rocks (16, 21). This change could result from either propagation of the fluvial system headwaters into an area with more alkaline igneous rocks or a shift to more locally derived volcanic debris, such as reworked volcanic rocks or ash deposits (21). Major element compositions do not indicate substantial chemical weathering in the sediment source area, which implicates a frigid or arid climate, a high-relief source area undergoing rapid erosion, or a combination of these factors (19, 21).

In general, the Yellowknife Bay formation (Fig. 4) is composed of fine-, medium-, and coarse-grained sandstones of basaltic composition. The Shaler outcrop (~125 cm thick) consists of a heterogeneous assemblage of interstratified platy coarse-grained beds comprising sandstones and likely pebbly units, separated by recessive, probably finer-grained intervals. Coarser-grained intervals are characterized by distinct decimeter-scale trough cross-bedding (Fig. 5A). Recessional intervals are marked by downwarping cracks that terminate upward at bedding planes and are probably filled with sediment from the overlying bed. The rock termed “Rocknest-3” is very fine-grained, finely laminated sandstone or siltstone with shrinkage cracks (Fig. 5B). Volcanic or impact-related base-surge deposition is excluded by the abundance of decimeter-scale and compound cross-bedding, the absence of stoss-side cross-stratification with preservation only of bedform toesets, and variable cross-bed dip directions. Furthermore, there are hierarchical scales of cross-stratification at the Shaler outcrop, indicating migration of superimposed bedforms of different scales. These attributes are most consistent with a former fluvial environment characterized by bedload and suspended load transport and variable, but net southeast flow directions. However, some eolian bedload transport is suggested by intercalated beds with pinstripe lamination. Most paleocurrent data are restricted to 90° of variability (fig. S1); however, some scatter to almost 180°, which is consistent with migration of three-dimensional (3D) superimposed bedforms (22). The inferred sediment transport direction suggests derivation of sediments from the direction of the Gale crater rim.

A fluvial interpretation is further supported by the tapered, likely sediment-filled cracks that are most easily accounted for by desiccation-induced shrinkage of finer-grained interbeds. These interbeds could represent either fluvial overbank deposits, slack water deposits in the troughs between bedform crests, or intercalated tongues of proximal lacustrine facies.

The Point Lake outcrop (~50 cm thick) is noteworthy for its pervasive centimeter-scale voids (Fig. 5C). These voids could possibly point to a volcanic origin, specifically a vesicular lava flow (23). Alternatively, it is possible that this facies also represents a pebbly debris flow or gas-charged intrusive sedimentary sill (24, 25). Scattered blebs of light-toned material were evaluated as calcium carbonate by ChemCam (19) and appear to fill voids and narrow fractures. Thus, it is possible that the rock could be a sandstone with leached nodular evaporites (26).

The Sheepbed and stratigraphically overlying Gillespie Lake members (Figs. 3 and 4) make up the exposed base of the Yellowknife Bay formation, and their contact has eroded to form a decimeter-scale distinctive topographic step observable in High Resolution Imaging Science Experiment (HiRISE) orbiter image data (Fig. 2A). The Gillespie Lake member consists of amalgamated, sheetlike sandstones. Bedding generally has a massive appearance, though poorly defined cross-bedding is present. The basal bed of the Gillespie Lake member is formed of poorly sorted, angular to moderately well-rounded, medium to very coarse sand of bulk basaltic composition (Fig. 5D). Some of the largest grains have translucent luster. Very little residual porosity between grains is evident, which suggests...
a high degree of cementation; what porosity does exist appears as sparse, millimeter-scale irregular vugs (void spaces). This basal bed has a sharp, erosional base that shows centimeter-scale scouring into the underlying Sheepbed member mudstones and appears to show lateral variation in its thickness. The poor sorting, massive bedding, and variability of grain shape in the Gillespie Lake sandstones are most consistent with fluvial transport and deposition. The sheetlike geometry of the beds, extending over hundreds of meters, and the absence of well-developed channel bodies may indicate deposition as distal fan lobes, as documented in examples from ancient alluvial fans on Earth (27).

The pebble conglomerate outcrops distributed across the HP map unit have an uncertain stratigraphic relation with respect to the Yellowknife Bay formation. On one hand, the conglomerate exposures occur at a topographically high level above flat-lying rocks of the Yellowknife Bay formation; the simplest interpretation would invoke superposition and, therefore, a younger age for the conglomerate than the Yellowknife Bay formation. However, regional mapping allows for, but does not require, an alternative possibility in which flat-lying Yellowknife Bay rocks unconformably onlap older rocks that underlie the HP map unit; in this interpretation, the conglomerate is relatively older. Unfortunately, outcrop between Yellowknife Bay rocks and the nearest conglomerate is very poor, and it is not possible to observe a contact. Therefore, both

---

**Fig. 4. Stratigraphy of the Yellowknife Bay formation plotted with elemental and oxide ratios measured by the Curiosity APXS instrument.** The Yellowknife Bay section was split into three members distinguished by lithological properties (facies, textures), chemical composition, and attributes observed from orbit by HiRISE. The stratigraphic column highlights differences in grain size between the Yellowknife Bay members and the presence of stratification styles; primary textures; and diagenetic textures including nodules, hollow nodules, raised ridges, sulfate-filled fractures, and vugs. APXS analyses are plotted as ratios to highlight compositional trends throughout the Yellowknife Bay formation. Average Mars crustal composition for each ratio (colored vertical lines) (20) is plotted for comparison to Curiosity APXS measurements.
options are feasible, but in either case, these rocks all belong to the same genetically related suite of fluvial-lacustrine sediments derived from the crater rim.

Sheepbed Mudstone Member

At a minimum, the Sheepbed member extends laterally across the width of the outcrop belt traversed by the rover: ~60 m. The Sheepbed member closely coincides with the BF map unit and from orbit is highlighted by its light tone and extensive meter- to decameter-scale fracture network. Tracing of the distinctive erosional profile of the Sheepbed–Gillespie Lake contact shows that the Sheepbed member probably extends around the full width of Yellowknife Bay and covers a minimum area of ~4 km². However, we presume the Sheepbed member extends beneath the overlying rocks of the Gillespie Lake member; therefore, these are highly conservative minimum estimates. A reference section localized near the Selwyn target (Fig. 3) yields a thickness of 1.5 m for the member. This is a minimum thickness because its base is not exposed.

A detailed traverse (Selwyn reference section) using Mastcam, ChemCam, Alpha Particle X-ray Spectrometer (APXS), and Mars Hand Lens Imager (MAHLI) measurements was conducted across the Sheepbed member for the purpose of providing context for the first samples obtained by drilling (Figs. 3 and 4). Observations revealed a patchy distribution of diagenetic (postdepositional) features, including nodules and veins, as discussed below. Mineralogic data show that the Sheepbed member has a substantial quantity of saponitic smectite clay minerals (~20%), probably formed by aqueous alteration of olivine (28). Geochemical results (19) show that both Sheepbed and Gillespie

Fig. 5. Sedimentary rocks of the Yellowknife Bay formation. (A) Shaler outcrop shows a variety of facies, including compound cross-bedding. The image was white-balanced and acquired by Mastcam-100 on sol 120. Image ID is 0120MR00075201302-00690E01_DXXX. (B) The Rocknest-3 rock, which represents the middle part of the Glenelg member, is fine-grained with planar lamination, shrinkage cracks, and millimeter-scale voids (well developed in the lower third section of the rock). This image is a subset of a mosaic of images that were white-balanced and acquired with Mastcam-100 on sol 59. Image IDs, as part of SEQID mcam00270, are 0059MR000270000103141E01_DXXX, 0059MR0002700103142E01_DXXX, 0059MR0002700203143E02_DXXX, and 0059MR000270030103144E01_DXXX. (C) Vuggy, medium-grained texture in the Point Lake outcrop (“Measles Point” target), middle of the Point Lake member. Note the thin fractures filled with light-toned material, interpreted as sulfate. ChemCam data show that white blebs, such as the one in the center, are composed of calcium sulfate. This focus merge product was acquired by MAHLI on sol 303, ID 0303MH000290000103786R00. (D) Medium- to coarse-grained sandstone at the Gillespie Lake outcrop (see Fig. 2B), basal bed of the Gillespie Lake member. This bed is composed of poorly sorted, moderately well-rounded, dark to light grains, some of which have glassy luster (lower left arrow). A small amount of vuggy porosity is evident (upper right arrow), but otherwise the rock appears well cemented. The image was acquired by MAHLI on sol 132, ID 0132MH0001580010101221E01. (E) Mudstone in Sheepbed member, “Wernecke target” (see Fig. 3). The rock has been brushed, revealing homogeneous, fine-grained texture. Outlines of nodules (black arrow), void spaces (gray arrow), and sulfate-filled voids can be seen, and only those voids connected by hairline fractures (white arrow) have been filled with sulfates. Note the surface scoring by brush bristles, indicating softness of mudstone. The image was acquired by MAHLI on sol 169, ID 0169MH0002080020102218C00. (F) John Klein drill hole (see Fig. 3) reveals gray-colored cuttings, rock powder, and interior wall. Note the homogeneous, fine grain size of mudstone and the irregular network of sulfate-filled hairline fractures. An array of eight ChamCam shot points can be seen. The diameter of the hole is 1.6 cm. The image was acquired by MAHLI on sol 270, ID 0270MH0002540050102794C00.
sediments were derived from a provenance with a composition similar to average martian crust and that experienced negligible chemical weathering before deposition at Yellowknife Bay. Relatively subtle differences exist between the lower and upper parts of the Sheepbed, such that the top exhibits higher Al2O3/TiO2 and Ni, consistent with a slight provenance change. A further change in trace elements (higher Cr, lower Ni and Ge), which occurs across the Sheepbed–Gillespie Lake contact, could result from either provenance differences or mineral sorting (e.g., chromite) associated with grain-size differences. Both APXS measurements and high-spatial resolution ChemCam targeted analyses provide evidence that crosscutting veins and fractures are composed of Ca-Sulfate (see below).

The highest-resolution MAHLI images were acquired on sol 150 (Ekwir) and sol 169 (Wemecke) after brushing of the outcrop (Fig. 5E). These images reveal a very fine grain size based on the outlines of darker grains, and nearly all discernible grains are finer than 50 μm. By definition, a mudstone is a fine-grained sedimentary rock composed of 50% or more particles smaller than 62 μm (29). Although we cannot directly resolve and observe these <50-μm grains, we do know that ~20% are clays. It seems likely that the entire Sheepbed member is finer than most facies observed by Curiosity during the traverse down to Yellowknife Bay. Drilling of the outcrop produces gray powder and cuttings that are substantially different in color from the modern surface (Fig. 5F). Inspection of the drill hole reveals a gray rock that is fine-grained and homogeneous in texture, with the exception of light-toned fractures filled with minerals.

Independent evidence for the fine grain size of the Sheepbed mudstone comes from inferences of the physical responses of brushing and measurements made during drilling. The rotary motion of bristles during brushing substantially scored the surface of the outcrop in a fashion that shows deflections (Fig. 5E) around apparently harder, embedded dark nodules, suggesting that the mudstone matrix is softer. Comparison with terrestrial analog data suggests weak to medium hardness for the mudstone (30). Additional estimates of rock hardness are provided by comparison of rover engineering testbed data derived from terrestrial analogs with drill hardness data from the Sheepbed member (31). These data sets suggest that the Sheepbed rock is comparable to fluvial-to-lacustrine siltstones and mudstones collected from the ~10-million-year-old Ridge Basin of southern California (buried to depths of several kilometers) but not as hard as feldspathic sandstones derived from the same basin or as soft as pure commercially available kaolinite.

Sheepbed mudstones contain a few very thin intercalated beds that resist erosion (Fig. 4). These interbeds have not been studied in detail, but Mastcam data show them to be 1 to 2 cm thick and with substantial lateral continuity, as some can be traced for more than 100 m. Over-all, the primary texture and grain size has a very uniform, massive appearance; it is well known, however, that lamination can be difficult to detect in many mudstones (29).

The very fine grain size, its apparently uniform distribution through the member, and the substantial lateral extent of centimeter-scale interbeds are all consistent with deposition of the primary grains due to settling from suspension, either from the atmosphere or a water column. The former might involve volcanic ash,olian dust, or very distal impact fallout. Because the composition of the Sheepbed mudstone is basic and we cannot ascertain the very finest grain sizes, it is hard to discount an airfall origin. However, mapping relations, regional context, and local sedimentologic constraints all point to a distal alluvial fan or proximal lacustrine setting. In this setting, sediment-laden fluvial flows can deposit extensive fine-grained deposits, either as overbank flood deposits or at their downstream termination where they enter a body of standing water, such as a lake. Here, the decrease in flow turbulence as flows thin overbank and spread when leaving a channel, or encounter the still water of a lake, leads to deposition of suspended fines. We favor the lake interpretation because of the lateral extent and thickness of the Sheepbed member, the absence of fluvial channel bodies laterally adjacent to mudstone beds, and the fact that the mudstone underlies the Gillespie Lake member fluvial sheet sandstones over a large areal extent. Given our limited observations, it is difficult to exclude the hypothesis that this lake may have been seasonally dry (playa), or whether it responded to longer-term wet-dry climatic fluctuations. However, the compositional data favoring low salinity for the lake waters (19) and specific diagenetic textures discussed below (cement-filled synaeresis cracks, rather than sediment desiccation cracks) suggest that it was perennially wet for the stratigraphic interval we examined.

Strata dominated by fluvial sediments that predate the advent of terrestrial vegetation on Earth are generally devoid of fines, except as occasional mud drapes that are preserved between sets of cross-stratified dune or bar deposits (32, 33). Sweeping of very broad and shallow channels that produce sheet flood deposits result in reworking of thin floodplain deposits that tend to not be preserved in the stratigraphic record. In addition, eolian reworking between flow events, in the absence of terrestrial vegetation to anchor fines, is also regarded as an efficient mechanism to sweep fines away from sites of deposition. Thus, a shallow lacustrine environment, which sequesters fine sediments over long time scales, is considered to be the most likely interpretation for the Sheepbed mudstone.

The grain size and composition may be inconsistent with typical Mars dust, which is even finer in grain size and characterized by SO3 contents approaching 7% (20, 34), rather than the Sheepbed mudstone, which is closer to 1% SO3 (19). Although it seems conceptually possible to deposit relatively thick intervals of dust (35, 36), this might not be expected on an alluvial fan that is intermittently active enough to result in the substantial amounts of coarser-grained sediment accumulation seen in the Yellowknife Bay formation. Furthermore, estimates of dust accumulation rates are very low [on the order of 10 cm per million years (37)], as compared with fluvial or even lacustrine sediment accumulation rates, which are orders of magnitude higher (38).

Sheepbed compositions likely discount an origin as pure volcanic ash. Apart from variation imposed by sulfate-rich diagenetic features, the Sheepbed is geochemically uniform with an adjusted volatile-free composition close to average martian crust (19). Individual volcanic ash eruptions might be expected to display some variation in composition, and it would be coincidental for individual eruptions to all have a composition essentially the same as the average crust. If the ~1.5-m-thick Sheepbed member represented a single eruption, this would require a local source that is not observed in the vicinity of Gale crater [probably within a few tens of kilometers for 1 m of thickness (39)].

**Diagenesis of the Sheepbed Mudstone**

A diverse set of diagenetic features that postdate deposition is observed in the Sheepbed mudstone member. Early diagenetic features include nodules, hollow nodules, and raised ridges (Figs. 6, A to C). These features are crosscut by later fractures, filled with light-toned cements (Fig. 6D) shown to be variably hydrated sulfate minerals based on ChemCam, APXS, Mastcam, and Chemistry and Mineralogy instrument (CheMin) data. Additionally, a dike-like feature known as the “snake” obliquely crosscuts the Sheepbed–Gillespie Lake contact and extends for several meters (Fig. 3).

Concentrations of nodules and hollow nodules have patchy distributions and pass laterally (Fig. 7) into mudstones that have raised ridges. Nodules are expressed as millimeter-scale protrusions of the outcrop with 3D differential relief suggesting crudely spherical geometry (Fig. 6A). The mean diameter of 4501 nodules is 1.2 mm, with minimum and maximum diameters of 0.4 and 8.2 mm, respectively. Brushing shows that nodules are more resistant to brush-induced etching and, thus, harder than the surrounding mudstone (Fig. 5E). Mastcam, MAHLI, and ChemCam Remote Micro-Imager (RMI) data show that nodules are dispersed from one another, cluster in patches (Fig. 7), do not form their own beds, and show no evidence of size grading, despite a broad range in diameters. These constraints suggest that the nodules are of concretionary origin rather than volcanic or impact lapilli (40, 41). Furthermore, no associated out-sized clasts that might be interpreted as potential bombs, or any breccias, are observed. Comparison of John Klein (fewer nodules and hollow
nODULES) AND CUMBERLAND (MORE NODULES AND HOLLOW NODULES) COMPOSITIONAL DATA INDICATES THAT NODULE AND HOLLOW-NODULE RIM GROWTH MAY HAVE INVOLVED IRON-BEARING COMPOUNDS SUCH AS THE MINERAL AKAGANEITE OR EVEN CLAY MINERALS (19, 28).

HOLLOW NODULES ARE MILLIMETER-SCALE CIRCULAR RIMS WITH HOLLOW CENTERS (FIG. 6B). THREE-DIMENSIONAL EXPOSURES SOMETIMES REVEAL PEDESTAL-LIKE STRUCTURES WITH A CIRCULAR RIM SURROUNDING A HOLLOW, BOWL-LIKE DEPRESSION. THE OUTCROP THEREFORE HAS A LOCALITY PITTED APPEARANCE, SUGGESTING EROSIONAL EXPOSURE OF APPROXIMATELY SPHERICAL Voids THAT HAD RESISTANT RIMS, SIMILAR TO THE HOLLOW Voids. RESISTANCE TO WEATHERING BY THE RIMS OF THE HOLLOW NODULES IS INDICATED BY THE PRESENCE OF LINEATIONS AND “WIND TAILS” CARVED INTO THE OUTCROP, PRESUMABLY BY EOLIAN SALTATION ABRASION. DEVELOPMENT OF PEDESTALS LIKELY RECORDS LOWERING OF THE OUTCROP SURFACE BY PROLONGED EOLIAN ABRASION. Mastcam, MAHLI, and ChemCam RMI data show that hollow nodules are regarded as void spaces preserved within the Sheepbed mudstone. However, the hollow nodules are distinctly different from millimeter-scale diagenetic vugs, such as in the Gillespie Lake member or Burns formation of Meridiani Planum (40), in that the hollow nodules are associated with a ubiquitous circumscribed rim. Spherical voids of this type have not been observed previously on Mars and perhaps relate to their ability to be preserved—in this case, within fine mudstone sediments. Two options are possible to explain the void space, which creates the hollow observed in outcrop: In the first hypothesis, the void space would represent a vanished mineral, whose higher solubility allowed easy dissolution during subsequent diagenetic fluid percolation events. Such minerals might have grown displacively in the sediment [for example, in evaporites (26)], thereby eliminating the need for the void to have been primary. However, no examples of filled hollow nodules were observed, with one very specific exception: Where hairline fractures filled with light-toned sulfate minerals intersect hollow nodules, the hollow nodules also are filled with sulfates. Otherwise, hollow nodules are devoid of any remnant of an earlier mineral. The sulfate-filled fractures represent a later phase of diagenesis (see below), and therefore, the sulfate minerals are not considered part of the primary environment. This allows for a second hypothesis in which the hollow nodules represent primary voids,
such as gas bubbles formed during or soon after deposition. Several mechanisms could generate gas during or after sedimentation, including diagenetic dissolution and precipitation reactions that might produce gas as a by-product. These might include hydrogen gas produced during authigenic clay mineral formation via olivine "saponitization" (25); ultraviolet (UV) photo-oxidation of reduced minerals, such as siderite, to produce authigenic iron oxide (e.g., magnetite) and hydrogen gas (42); pressure-induced release of dissolved gas from sedimentary pore fluids; and processes that reflect distinct Mars environments, such as boiling of water in the presence of critically low atmospheric water vapor pressure. Data are insufficient to distinguish among these possibilities. However, the last of these can be discounted by the presence of thin interbeds within the Sheepbed mudstone, which suggests that wholesale churning of the mudstone did not occur. A final possibility considers the potential role of microbes, if life had ever evolved on Mars. Terrestrial sediments are pervaded by microbes, which produce a variety of gases that become trapped as bubbles where lithification is early and rapid (43). However, it should be clear enough that this mechanism can only be invoked as a serious possibility after all other abiotic hypotheses have been discounted. This is not the case for our current data set, and we include this only for the sake of completeness.

Raised ridges (44) are narrow, curvilinear ridges that weather in raised relief, and, as mentioned above, they substitute laterally for nodules and hollow nodules (Fig. 7). The raised ridges are restricted to the Sheepbed mudstone, but one poorly constrained example was noted at a higher stratigraphic level (observed only from a distance; exact stratigraphic position and facies are uncertain). Measurement of 1619 raised ridges in the Sheepbed suggests that they extend at least several centimeters in length and have a mean width of 2.7 mm, with maximum widths of up to 5.8 mm. Raised ridges have spindle-shaped, pointed terminations (Fig. 6C). Most have subvertical orientation but can dip more gently, down to 45° or less, and their strike trends in all directions (Fig. 6C). Intersections of 90° between ridges are common. A distinctive attribute is that most ridges show internal banding, which contours the trend of the ridge, following closely all local deviations, including right-angle bends. Two parallel bands are most common, although three to four are also observed (Fig. 6C). Raised ridges are most simply interpreted as early diagenetic cracks that formed in consolidated or even partly lithified mudstone, then filled with one or more generations of cement that isochronously encrust the margins of the cracks. This infilling material has greater resistance to eolian erosion than the mudstone, resulting in its expression as ridges. ChemCam and APXS analyses have identified elevated Mg, Fe, Si, Cl, Li, and Br in the raised ridges, but insufficient evidence exists to confidently identify specific mineral phases (19). A strong correlation exists between Mg, Fe, and Cl, possibly indicating that a chloride phase may be present, but if so, it can only explain a small amount of the Mg and Fe enrichment. Alternatively, the correlation could result from a phase other than a chloride that contains substantial Cl. For example, CheMin data suggest the presence of akageneite (28).

Taken alone, the development of very early cracks in fluvial-to-lacustrine mudstones might be most simply explained by desiccation of wet sediment: Generally, desiccation cracks have polygonal geometry. Therefore, the nonpolygonal geometry of the cracks is unexpected, as are the isopachous, banded materials that fill in the fractures. Furthermore, the abundance of raised ridges is anticorrelated with the abundance of nodules and hollow nodules, suggesting that all three phenomena are genetically related, which is not observed for desiccation cracks on Earth. An alternative mechanism proposes that syn-depositional pore fluids (perhaps mixing with surface runoff waters) may have been important in driving diagenetic reactions that triggered early mineral precipitation, gas production, and volume contraction close to the sediment-water interface. On Earth, a related but poorly understood process known as “synaeresis” is thought to relate to clay mineral flocculation during mixing of saline and less saline waters, resulting in differential contraction of the substrate (45). Seismic shaking, perhaps induced by impacts on Mars, may help facilitate this process (46). The result is spindle-shaped cracks, a few centimeters long, that look very much like the Sheepbed raised ridges. In most cases on Earth, the cracks are filled by other sediments; however, in one very particular instance known as “molar tooth structure,” spindle-shaped cracks and related sub-spherical voids are filled with mineral (calcite) cement. The origin of subaqueous cracks on Earth is poorly understood, though the involvement of gas in generating the cracks and voids...
represented by molar tooth structure is likely (43, 47). As with the hollow nodules, a number of processes could generate gases in martian sediments. In general, the distribution of subaqueous shrinkage cracks reflects differential strength of the substrate materials, which may similarly be represented in the Sheepbed member by the spatial segregation of the nodules and hollow nodules versus raised ridges.

A distinct feature within lower Yellowknife Bay strata is a dike-like, dark-toned rock unit referred to as the “snake,” named after the target Snake River (see Fig. 3). This feature extends from the lowest stratigraphic level of the exposed Sheepbed member, crosses the Sheepbed–Gillespie Lake contact, and tapers out within the middle of the overlying Gillespie Lake member (Figs. 3 and 4). The snake is 6 to 10 cm wide and can be traced across bedding for ~5 m, cutting up through almost 1 m of stratigraphic section. MAHLI images of unbrushed parts of the snake suggest that it has a fine-grained clastic texture, but with larger fragments present suggestive of intraclasts (fig. S2). Elemental data show it to be similar in major elements but distinct from the Sheepbed member in trace element abundances (19). The snake can be traced to its stratigraphically highest position, where it terminates in a small anticline. At this terminus, thicker, massive beds extend laterally away from the core of the anticline. The snake has several possible interpretations, including a narrow igneous dike of basaltic composition; a large-scale crack that is filled from above, perhaps associated with subaerial exposure or ice wedging; or a sedimentary intrusion associated with compaction and dewatering of the mudstone or subadjacent strata.

The fine-grained, basaltic composition of the snake makes it hard to exclude an igneous intrusion with basaltic composition. The feature is so thin that grain-size variations consistent with chilled margins would be unexpected at scales within MAHLI’s limit of resolution; the entire dike would be expected to be very fine grained. Filling from above is discounted due to the presence of the small anticline, which suggests injection of fluidized material from below rather than settling of sediment from above. In addition, no evidence of layering, suggestive of downward percolation of sediments, is observed within the feature. Furthermore, no other crack-like features are observed to extend downward from a common stratigraphic surface. The third possibility—intrusion of plastically deformed sedimentary materials—occurs in some sedimentary environments with high sedimentation rates (24, 25, 48, 49). Upward and lateral injection of compacting muds and sands is most commonly expressed as dikes and sills that both crosscut strata and intrude along bedding planes. The similarity of both composition and texture to that of the Sheepbed mudstone, the presence of possible intraclasts, and upward deflection of strata at its terminus are all consistent with sedimentary injection (24, 25). This suggests a sediment accumulation rate for the Yellowknife Bay formation (or sediments below it) that was high enough so that pore fluid pressures built up to the point where expulsion along discrete zones of weakness, rather than along grain boundaries, was the preferred pathway for escape of compacting sediments and interstitial pore fluids. As the porosity and permeability of the sediment was reduced via compaction and cementation, the strata may have ruptured, allowing fluids to escape and form sedimentary dikes and sills. Finally, this process could have been aided by impact-induced seismic activity (50).

Fractures filled with light-toned sulfate cements also are regarded to have formed later in the diagenetic sequence because they cut the entire Yellowknife Bay formation. In contrast to the raised ridges, the sulfate-filled fractures are flush, even slightly depressed, with respect to adjacent unfaulted outcrop (Figs. 6 and 7). Sulfate-filled fractures have highly diverse orientations spanning from vertical to subhorizontal; range in length from less than 1 cm to more than 30 cm; and range in width from “hairline” (submillimeter) to 8 mm, with a mean width of 2.3 mm (Figs. 5E and 6D). MAHLI images of the John Klein drill hole show that sulfate-filled fractures of hairline width have complex orientations with horizontal as well as vertical trends (Fig. 5F). Where these hairline-width fractures intersect hollow nodule void spaces (Fig. 5E), the latter are also filled with hydrated and anhydrous calcium sulfate minerals, as determined by CheMin, ChemCam, and APXS data (19, 28). At a larger scale, the observation of fracture-filling hydrated sulfate mineralogy can be extended through Mastcam observations. Calibrated Mastcam spectra show evidence for hydration associated with most but not all of the fracture fills, including limited hydration in hairline fractures that penetrate and fill the void space of hollow nodules (28).

To form, the sulfate-filled fractures first require lithification of the Sheepbed and Gillespie Lake members to allow applied stress to cause brittle strain of the bedrock (51). Once open, the fracture networks then act as conduits for fluid transport, resulting in precipitation of cementing minerals within these initially low permeability sedimentary rocks. The fracture networks were possibly created by hydraulic fracturing due to high fluid pressures that would have been obtained during burial of Yellowknife Bay strata (51). The variation in hydration state of vein-filling sulfate mineralogy between gypsum, bassinite, and anhydrite could reflect primary variations in environmental conditions during deposition or, alternatively, diagenesis associated with burial and/or desiccation during subsequent erosion and exposure (28).

A final observation regarding later diagenesis concerns the Gillespie Lake sandstone member, which shows evidence for possible secondary porosity. Irregular vugs larger than the diameter of the average grain size (Fig. 5D) suggest that larger grains, or perhaps clusters of grains, were leached during fluid circulation. Alternatively, it is possible that these vugs represent intraclasts of mudstone that degraded by weathering. Another possibility is dissolution of preferentially more soluble early diagenetic minerals; however, the irregular shape of the vugs is not consistent with dissolved evaporite crystals.

The diagenesis of the Sheepbed member suggests a complex aqueous history involving at least two distinctly different water masses. After emplacement in distal alluvial-to-lacustrine environments, pore spaces in primary sediments were occluded by cements, and early diagenetic hollow nodule voids (gas bubbles?) may have been formed, along with concretions. At approximately the same time, nonpolygonal fissures in the lithifying sediment opened up and became lined with void-filling isopachous rim cements. All of these events, with the exception of hollow nodule void formation, must have occurred much of the primary porosity. This episode of diagenesis did not substantially change the bulk rock chemistry of these units relative to average martian basalt and are thus considered to have involved isoochemical alteration (79). This suggests that clay mineral and magnetite formation happened largely in situ, as a result of alteration of olivine to form authigenic saponite smectite (19, 28). In addition to pore-filling cement, it is possible that these minerals also precipitated as concretions, as well as isopachous rim cements within raised ridge fractures. After lithification, fracture porosity was created that was then filled with a distinctly different fluid that resulted in precipitation of sulfate cements (19, 28). The absence of elevated sulfate abundances in the Sheepbed mudstone, except for within these fractures, indicates that cementation and permeability reduction of the mudstone was extensive enough so that sulfate-rich fluids percolating through fractures and hairline fractures did not invade the mudstone or sandstone matrix (19, 28). The first diagenetic fluid, possibly derived from the waters that transported sediments, was dominated by dissolved silicate and iron oxide minerals. The second, subsequent fluid was dominated by sulfates and perhaps sampled a broader, basinwide hydrologic system. CheMin and Sample Analysis at Mars instrument (SAM) data additionally point to a substantial x-ray amorphous fraction of material that could have been involved in diagenesis, as well as potential sulfide minerals (28, 52).

Sheepbed Mudstone: Record of Habitable Environment

The regional geologic context, sedimentologic framework, and geochemistry and mineralogy of the Sheepbed mudstone all point to an ancient environment that would have been habitable to a broad range of prokaryotic microorganisms. The relatively neutral pH indicated by clay mineral stability (28); high water activity indicated by low salinity for primary and early
diagenetic environments (19); the variable redox states indicated by presence of magnetite, sulfate, and sulfide minerals and compounds (28, 52), and the apparent long duration of the aqueous environment(s) all support this interpretation.

The Sheepbed mudstone closely coincides with the BF map unit (Fig. 1), suggesting that this rock unit may have extended beyond the confines of Yellowknife Bay and minimally covered an area of ~30 km², not including buried or eroded equivalents. Repeated flows of water (17) and the likely presence of a body of standing water point to a sustained habitable environment. The durations of the primary, early diagenetic, and later diagenetic aqueous environments were substantial enough to create geologic and geochemical fingerprints of prolonged fluvio-lacustrine and diagenetic processes markedly similar to those that formed commonly during early Earth history (32, 53, 54).

A rough estimate of the minimum duration of the lacustrine environment is provided by the minimum thickness of the Sheepbed member. Given 1.5 m, applying a mean sediment accumulation rate for lacustrine strata of 1 m per 1000 years (38) yields a duration of 1500 years. Lacustrine sediment accumulation rates vary by several orders of magnitude (38); thus, the hypothesized lake could represent hundreds to tens of thousands of years. If the aqueous environments represented by overlying strata are considered, such as the Gillespie Lake and Glenelg members, then this duration increases. Indeed, the regional geologic context suggests that the Yellowknife Bay formation may have formed, the additional presence of Fe³⁺ relative to oxidized sulfur pointing to a plausible terrestrial biosphere founded on chemolithoautotrophy at Yellowknife Bay.

As a first step, it is useful to assess the key nutrients required to support terrestrial bacteria and archaea (66). The defining chemistry is inorganic: elemental inventory, liquid water, redox potential (EH), pH, redox couples, and a diversity of chemical compounds. Organic molecules are not required environmental constituents because they can be synthesized de novo through the primitive autotrophic pathways, such as methanogenesis and acetogenesis (67). We have measured H, O, S, C, N, and P in minerals and other compounds with the APXS, ChemCam, CheMin, and SAM instruments, as well as important metals such as Fe, Mg, and Mn (19, 28, 52). All but P are observed in SAM evolved gas analysis (EGA) data as volatiles, and all but P and N are known to be part of mineral structures observed in CheMin data. We do not have the capability to determine whether P would have been bioavailable, and CheMin observed no highly soluble P-bearing minerals. On the other hand, CheMin data indicate substantial breakdown of olivine in the mudstone at Cumberland (28), and P can be a trace-to-minor element in that mineral (68), suggesting potential P mobility during diagenesis. Nitrogen-bearing compounds, in both reduced and oxidized forms, were measured by SAM during EGA (52). Evolved NO (mass-to-charge ratio = 30) has an abundance that is substantially above background, pointing to a likely source within the mudstone. Bioavailable N could conceivably have been derived from the atmosphere via fixation by sulfide minerals during reactions similar to that seen in pyrrhotite, pyrite, and maghemitite assemblages on Earth (69, 70).

SAM EGA data from John Klein show carbon to be present, either in crystalline (carbonates?) or nanophase iron oxide indicated by combined APXS/ChemCam and SAM data (19, 28, 52) provides the other half of an iron-based redox couple in the Sheepbed mudstone.

As a second step, we identify plausible redox couples represented by iron and other compounds preserved in the Sheepbed mudstone that might have comprised basic energy-yielding reactions for an ancient microbial community (66). The presence of both sulfur and iron is indicated by ChemCam, APXS, CheMin, and SAM data. Further, observation of key inorganic volatiles such as H₂O, H₂S, SO₂, H₂, and CO₂, generated during SAM pyrolysis (52), suggests a wider range of redox conditions for the surface of ancient Mars than previously recognized based on Viking, Phoenix, and Mars Exploration Rover data (71–74). For example, SAM analysis of the John Klein sample shows higher H₂S/SO₂ average ratios than were found for the Rocknest soil sample: 0.06 for John Klein (52) versus 0.01 for Rocknest (73). These data suggest a higher proportion of reduced sulfur relative to oxidized sulfur pointing to a plausible redox couple for prokaryotic respiration.

Iron also presents intriguing possibilities for redox coupling. ChemCam analyses indicate the presence of a substantial quantity of likely authigenic magnetite (~7%) of crystalline components) in Sheepbed mudstones (28). The presence of an authigenic, partially reduced Fe-oxide phase in a martian sedimentary rock represents a notable departure from previous secondary Fe-mineral detections on Mars, where ferric iron has proven to be the dominant redox state (76–78). The magnetite measured by CheMin does show evidence for oxidation of some of its ferrous iron to form the ferric defect-spinel maghemite (28). The gray color of the freshly exposed Sheepbed mudstone (Fig. 5F) contrasts sharply with the reddish color of the freshly exposed, highly oxidized, hematite-bearing rocks of Meridiani Planum (79), emphasizing the lower oxidation state of iron in the Sheepbed mudstone. There are a number of potential mechanisms for the production of authigenic magnetite, all of which are promoted by waters with relatively low Eh and neutral to alkaline pH (80). Under such conditions, aqueous Fe²⁺-hydroxide species can precipitate and ultimately transform to magnetite. Perhaps not coincidentally, neutral-to-alkaline pH conditions also are likely to promote the formation of clay minerals. Potential authigenic magnetite formation pathways include UV-promoted reactions with dissolved Fe²⁺ in the water column (81) or with carbonate minerals in the sediment (42), and partial oxidation of dissolved Fe²⁺ by dissolved O₂ (80). Perhaps the most likely scenario is via clay formation and saponitization (28). However the magnetite may have formed, the additional presence of Fe³⁺ in nanophase iron oxide indicated by combined APXS/ChemCam and SAM data (19, 28, 52) provides the other half of an iron-based redox couple in the Sheepbed mudstone.

Salinity provides another important constraint on habitability because it affects water activity, which, when low, can restrict cellular physiology (82–84). All natural waters contain dissolved ions that, through their interactions with water molecules, limit the availability of H₂O for hydration reactions. Water activity is defined by microbiologists as a = n₁/n₂ + n₃, where n₁ equals moles of water and n₂ equals moles of solute (82). Most terrestrial organisms cannot survive below a = 0.9, a few halophilic
bacteria grow at \( a_w = 0.85 \), and some archaea can grow at \( a_w = 0.75 \) (83). In the Burns formation at Meridiani Planum, the abundance of calcium and magnesium sulfate minerals detected by the Opportunity rover is so great that it conservatively reconstructs to an ancient water activity of \( a_w = 0.78 \) to 0.86, and possibly as low as \( a_w = 0.5 \) (85). This shows that water activity was so low during deposition and diagenesis of the Burns formation that even though water was present, the environment would probably have been uninhabitable to all but the hardest halophiles (86). In contrast, the Sheepbed mudstone provides evidence for both low salinity sediment-transporting water and early diagenetic water, given its very low sulfur and chlorine content (19). It is possible that small amounts of chloride salt were present (19, 28); however, these were in low enough abundance (<1 to 2%) so as to not substantially reduce water activity and create a challenge for prokaryotic microbes. Higher salinities are indicated for the waters that percolated through late diagenetic fractures; however, these were probably of modest salinity given their exclusively calcium sulfate composition (85). On Earth, calcium sulfate precipitation is common in evaporitic environments that thrive with diverse microorganisms (87). Furthermore, there is evidence that halophiles may resist the destructive effects of radiation (88), thought to limit habitability in the martian surface environment (89).

Finally, estimates of pH are similarly important for understanding habitability. Again, in the Burns formation at Meridiani Planum, the presence of jarosite indicates low pH with ancient waters that contained sulfuric acid (40). However, such low pH does not discount the presence of life; terrestrial analog environments show that microbes can survive under these conditions because they have adapted their biochemistries to maintain near neutral conditions internally (90). Nevertheless, the presence of more neutral waters allows a broader range of microorganisms to be viable. The presence of clay minerals in the Sheepbed mudstone, the absence of any evidence for AI mobility, and the absence of iron sulfate minerals, even in the sulfate-filled late diagenetic veins, indicates a relatively neutral pH. This neutral pH could have existed for all phases of aqueous history, from the primary waters of deposition that may have created a body of standing water, to early diagenesis, and through the close of late diagenesis.

At Yellowknife Bay, there is no hint of the strongly acidic conditions that have been thought to especially describe the planet’s younger history of aqueous alteration, sedimentation, and habitability (74, 83, 91). The record of aqueous activity at Yellowknife Bay is likely prolonged and complex, involving several stages of diagenesis, including clay formation, that culminated with precipitation of calcium sulfate salts in veins, but without attendant indicators of acidic waters such as iron sulfates. The simplest interpretation of the sequence of diagenetic events would involve progressive desiccation of mildly saline, pH-neutral waters—a very Earth-like scenario (92). Such conditions have been envisaged for the very early history of Mars (97), but it is only recently that they have been considered viable for a younger age (7, 93, 94). The surprising result is that the stratigraphy of Yellowknife Bay may not only preserve evidence of a habitable environment, but one that is relatively young by martian standards. In the most conservative scenario allowed by geologic mapping, the Yellowknife Bay formation represents part of the older fill of Gale crater, and therefore is roughly Early Hesperian in age (6), perhaps overlapping with or postdating times of bedded sulfate formation elsewhere on Mars. This would indicate that times of sustained surface water, neutral pH, and authigenic clay formation extended later into Mars’ history. The potentially young age of clay formation (and habitability) does not invalidate the general trend that most rocks that interacted with water early in Mars’ history produced clays, and those that interacted later produced sulfates. However, much like Earth’s time-dependent records of iron formation (95, 96) and carbonates (97, 98), it points to the need to understand those special conditions, which allow a distinctive aqueous environment to persist for broad spans of geologic time or to recur when the favorable conditions again emerge. Curiosity’s detection of a relatively young and markedly Earth-like habitable environment at Gale crater underscores the biological potential of relatively young tholus-lacustrine environments.

**References and Notes**

10. This decision was made by the entire MSL Science Team with strong consensus to drive a relatively short distance (~500 m) to examine rocks with higher thermal inertia values that also had an apparently strong spatial association with the AF unit. The prediction based on mapping was that fluvial and/or lacustrine rocks potentially derived from the crater rim might be encountered. The strata exposed at the base of Mt. Sharp are still considered to be the primary mission objective, and the team has established a departure date from Yellowknife Bay of the first week in July.

11. The names used for rock and soil targets studied by Curiosity and reported in this paper are derived from established rock formations of northern Canada. In turn, these names derive from names of local geographic features where they occur, per convention, such as mountains, streams, lakes, bays, etc. This choice of naming scheme celebrates the city of Yellowknife, Northwest Territories, long known to be a port of departure for geologic mapping expeditions into some of the oldest rocks of North America. Yellowknife crater was designated by the International Astronomical Union, and Yellowknife Bay demarcates the area into which Curiosity descended to study its geologic history.

12. A base map was created based on 25-cm-per-pixel HiRISE visible image data, 1-per-pixel elevation data, and 100-m-per-pixel THEMIS Emission Imaging System data that was subdivided into 14.2- by 1.2-km (0.025°) quadrangles and mapped in detail by more than 30 team members. The map group was compiled, consolidated, and iteratively refined into a single GIS project.

13. In addition, minor units of eolian fill and/or bedforms and ejecta blankets adjacent to larger craters are present but are not discussed further.

14. Bradbury Landing refers to the patch of ground where Curiosity touched down on the surface of Mars. It commemorates the noted science fiction writer Raymond Bradbury and was designated by NASA.

18. The morphology of the “bay” is the result of postdepositional erosion, perhaps by eolian processes, as shown by the exposures of stratified rock that record dissection. These are eroded rocks and not, for example, shoreline berms. Therefore, the present-day topography does not reflect that at the time of deposition of those strata.

Exploring Martian Habitability

Acknowledgments: We are indebted to the MSL Project engineering and management teams for their exceptionally skilled and diligent efforts in making the mission as effective as possible and enhancing science operations. We are also grateful to all those MSL Science Team members who participated in tactical and strategic operations. Without the support of both the engineering and science teams, the data presented here could not have been collected. Some of this research was carried out at the Jet Propulsion Laboratory, California Institute of Technology, under a contract with NASA. Data presented in this paper are archived in the Planetary Data System (pds.nasa.gov).

**Drill testing of rock hardness**

Data collected during terrestrial drill testing on relevant analog samples provide constraints on the physical properties of the rocks drilled at the John Klein and Cumberland drill sites on Mars. The first two analogs consisted of a feldspathic sandstone and a mud/siltstone collected from the Pliocene age Ridge Basin Group, north of the Golden State Highway Old Road, below the Pyramid Lake Dam north of Castaic, CA. These rocks are estimated to be 5-10 million years old, and buried to depths of several kilometers. The third was a pure kaolinite, obtained from the Standard Industrial Mineral mine in Bishop, CA, and the fourth was a large sample of anhydrite-gypsum collected from the Fish Creek Gypsum deposit located in the Salton Trough, south west of the Salton Sea, CA and owned by U. S. Gypsum Mine company.

Drill testing was performed in a drill hardware testbed at the NASA Jet Propulsion Laboratory that houses a flight duplicate MSL drill assembly (100). The drill is mounted to a stage that holds the drill system in place as the rotary percussion drill bit and surrounding sample acquisition tube are fed into rock samples using flight-like drilling algorithms. The drill and its supporting hardware are contained within a vacuum chamber and tests were performed under Mars ambient atmospheric pressure (~10mbar) during drill testing. In an attempt to more closely replicate the likely hydration state of rocks on Mars, all analogue rock samples were baked in an oven at 110°C for a period not less than 2 days prior to drilling in order to drive off adsorbed and loosely bound water to better resemble conditions expected to be present on target rocks on Mars.

While the *Curiosity* rover does not possess a dedicated instrument for direct determination of rock hardness, a hardness test procedure that uses the drill hardware for *in situ* determination of rock hardness and cohesiveness has been developed. MSL “Hardness tests” are performed by measuring the depth of penetration of MSL’s spade-shaped drill bit tip after a number of discrete motions that result in drill-rock interaction with a non-rotating drill bit. These include depth measurements after the drill bit is loaded against the rock surface with a 130N force, after the drill is “tapped” against the rock with a single tap of the percussion actuator, and six subsequent depth of penetration measurements after the drill bit is advanced (without rotation) into the rock at increasing levels of percussion energy. The 6 percuss levels increase in energy with level 1-6 having 0.05 J per blow, 0.20, 0.31, 0.45, 0.61, to 0.81 J per blow, respectively. The results of these hardness tests provide insight into the relative resistance to penetration of various analogue rock samples for comparison to data collected during drilling operations on Mars. **Figure S3** plots our hardness test results for the four analog samples discussed above along with hardness test results from the John Klein and Cumberland drill samples collected by the *Curiosity* rover on Mars. Note that hardness tests were performed at two locations on the John Klein rock face; one for a mini-drill hole (~20 mm total penetration depth) and one for the full-depth drill hole, from which sample was
collected and delivered to *Curiosity’s* onboard analytical instruments. For the Cumberland hardness test, the drill bit tip appears to have advanced deeper into the rock for a given step in the test procedure. In fact, the Cumberland hardness test was terminated at Step 8 because a depth >0.8mm was achieved. Altogether these observations suggest that the Cumberland rock target was less resistant to penetration (i.e., softer) than the John Klein target.

A somewhat different picture emerges from Rate of Penetration (ROP) data, which measures the speed at which the drill bit and its surrounding sample acquisition tube are fed into a rock. While this data is a complex function of the intrinsic rock hardness, the cohesive strength of rock, and the engineering parameters of the drill system, it is interesting to compare data from our analogue samples to ROP data collected on Mars. ROP data collection occurs during rotary-percussive drilling, after the hardness test is performed and after a series of rotary-percussion “hole start” motions are performed that effectively create a shallow pilot hole to keep the drill bit from walking across the rock face during the drilling operation. As shown in Figure S4, the John Klein and Cumberland ROP data fall in between the feldspathic sandstone and kaolinite test data, and appear most similar to data collected on the Ridge group mud/siltstone and the anhydrite-gypsum from the Salton Sea. It is important to note that for *in situ* drilling operations on Mars, the percussion level was intentionally limited to a level lower than the drill system’s maximum percussion level, owing to hardware safety concerns for first time drilling operations. These limits were not applied during analogue drill testing on Earth. Therefore, it is possible that a faster ROP could have been realized during John Klein drilling operations had the percussion level been allowed to advance to higher levels. Therefore, the ROP data for John Klein should probably be considered a lower limit on the ROP for this *in situ* drilling operation.
Fig. S1.

Three-dimensional bedding orientation measurements were extracted from Sol 120 Navcam images of the outcrop, which have been vertically projected in this map. Measurements were made via orthogonal regression, via the method of Lewis et al. (99). Dip marks denote individual measurements of bedding traces, shown in white. The polar plot shows each measurement that satisfied our error constraints (N=25), along with the mean bedding attitude in blue. In general, cross-strata at Shaler dip to the southeast, at a mean dip of 7 degrees, oriented 64 degrees south of east. Although individual measurements show some scatter in dip azimuth, nearly all beds are oriented within 90 degrees of the inferred mean flow direction, consistent with fluvial transport and associated bedform geometries. See Supplementary Text, below, for image IDs.
Fig. S2
Texture of the “snake” as seen by MAHLI on Sol 149 (6 Jan 2013). Note uniformly fine grain size and presence of pits that may reflect void spaces and, in some cases, erosion of softer components that may represent intraclasts. Image ID: 0149MH0000750010101287C00.
Fig. S3
Hardness test results for analogue samples plotted together with the John Klein and Cumberland data on a graph of cumulative depth of cut (mm) versus Hardness test step #.
Fig. S4
Rate of Penetration (ROP) results for analog samples plotted together with the John Klein and Cumberland data on a graph of ROP (mm/min) against drill depth (mm).
### Table S1.
Stratigraphic Nomenclature

<table>
<thead>
<tr>
<th>Name</th>
<th>Unit Description</th>
<th>Exposure and Contacts</th>
</tr>
</thead>
<tbody>
<tr>
<td>Glenelg member</td>
<td>Intermixed facies, including those represented by the following outcrops:</td>
<td>• Caps Yellowknife Bay formation stratigraphy. The “cratered surface” map unit, to the southeast of Yellowknife Bay, may represent the expression of the upper surface of a resistant bed near the top of the formation, or the top of the formation itself.</td>
</tr>
<tr>
<td>1) Bathurst Inlet outcrop</td>
<td>• Centimeter- to decimeter-thick beds</td>
<td>• Upper beds (e.g. Bathurst Inlet outcrop) weather resistantly, and typically overlie slopes covered with scree, which may be underlain by facies similar to those in the Shaler outcrop.</td>
</tr>
<tr>
<td></td>
<td>• Grain size not resolvable with MAHLI; likely fine sand, silt, or clay-sized.</td>
<td>• Facies represented by the Point Lake and Rocknest outcrops are exposed as discontinuous layers and a ≤200 m² platform of resistant beds.</td>
</tr>
<tr>
<td></td>
<td>• Basaltic composition with a significant enrichment in alkaline elements.</td>
<td>• Lower contact: sharp with the underlying Gillespie Lake member.</td>
</tr>
<tr>
<td>2) Shaler outcrop</td>
<td>• Centimeter- to decimeter-thick beds with variable resistance to erosion</td>
<td>• Upper contact: not exposed, or consists of the geomorphic cratered surface.</td>
</tr>
<tr>
<td></td>
<td>• Grain size varies from finer than fine sand up to granule, sorted into discrete layers.</td>
<td></td>
</tr>
<tr>
<td></td>
<td>• Diverse sedimentary structures, including planar lamination, low angle truncations, and trough cross stratification; rare fine-grained layers have vertical cracks filled with more resistant sediment.</td>
<td></td>
</tr>
<tr>
<td></td>
<td>• Downward-tapering sediment-filled cracks interpreted to have formed by desiccation.</td>
<td></td>
</tr>
<tr>
<td></td>
<td>• Basaltic composition</td>
<td></td>
</tr>
<tr>
<td>3) Point Lake outcrop</td>
<td>• 20-50 cm-thick layers of unknown origin</td>
<td></td>
</tr>
<tr>
<td></td>
<td>• Meter-long fractures define meter-scale polygons; weathered surfaces are rough.</td>
<td></td>
</tr>
<tr>
<td></td>
<td>• cm-scale vuggy porosity; rare bright, sulfate-filled fractures</td>
<td></td>
</tr>
<tr>
<td></td>
<td>• Basaltic composition</td>
<td></td>
</tr>
<tr>
<td>4) Rocknest outcrop</td>
<td>• Decimeter-sized rocks of unknown origin</td>
<td></td>
</tr>
<tr>
<td></td>
<td>• Some rocks show faint planar lamination to low angle cross</td>
<td></td>
</tr>
</tbody>
</table>
| **Gillespie Lake member** | **Decimeter-thick beds of uniformly smooth weathering sandstone;**  
| | **Meter-long fractures define meter-scale polygons;**  
| | **Medium to very coarse sand with diverse grain colors and some translucent grains at base of the unit**  
| | **Hints of small-scale cross stratification including possible ripple crests on bedding planes.**  
| | **Rare millimeter-scale bright, sulfate-filled fractures.**  
| | **Basaltic composition**  
| **Sheepbed member** | **Well exposed and laterally continuous regionally.**  
| | **Lower contact: sharp with centimeters of relief; lowermost bed always caps a small scarp, often overhanging. Contact is nearly horizontal for 100’s m to the east and northeast.**  
| | **Upper contact: sharp and well exposed under the Point Lake outcrop, but poorly exposed elsewhere.**  
| | **Decimeter-thick beds with variable resistance to erosion**  
| | **Abundant meter-long fractures define meter-scale polygons; fractures are centimeters to decimeters wide and sand-filled.**  
| | **Dominant grain size in upper 50 cm is below the resolution of MAHLI, likely silt to clay-sized.**  
| | **Variable concentrations of bright cement-filled fractures, hairline fractures, and millimeter-scale bright spherical “hollow nodules”, all filled with calcium sulfate.**  
| | **Dark, raised, intersecting ridges frequently rise above centimeter-scale polygons in meter-diameter patches. Ridges dip in various directions, have a composition similar to that of the host rocks, and show a small magnesium enrichment.**  
| | **Meter-scale patches contain high concentrations of millimeter-scale nodules, interpreted as concretions. Concretions have the same color as raised ridges. Hollow nodules are also present, as well as some**  
| | **The upper 50 cm of this unit weathers recessively and is well exposed to covered in loose sand.**  
| | **Lower contact: not defined**  
| | **Upper contact: sharp with centimeters of erosional relief, often overhanging. Regionally mappable due to topographic expression.**  

filled with calcium sulfate.
- Basaltic composition with ~20% smectite, ~50% igneous minerals; and ~30% X-ray amorphous material. Elevated magnetite likely authigenic.

References and Notes

10. This decision was made by the entire MSL Science Team with strong consensus to drive a relatively short distance (~500 m) to examine rocks with higher thermal inertia values that also had an apparently strong spatial association with the AF unit. The prediction based on mapping was that fluvial and/or lacustrine rocks potentially derived from the crater rim might be encountered. The strata exposed at the base of Mt. Sharp are still considered to be the primary mission objective, and the team has established a departure date from Yellowknife Bay of the first week in July 2013.

11. The names used for rock and soil targets studied by Curiosity and reported in this paper are derived from established rock formations of northern Canada. In turn, these names derive from names of local geographic features where they occur, per convention, such as
mountains, streams, lakes, bays, etc. This choice of naming scheme celebrates the city of Yellowknife, Northwest Territories, long known to be a port of departure for geologic mapping expeditions into some of the oldest rocks of North America. Yellowknife crater was designated by the International Astronomical Union, and Yellowknife Bay demarcates the area into which Curiosity descended to study its geologic history.

12. A base map was created based on 25-cm-per-pixel HiRISE visible image data, 1-m-per-pixel elevation data, and 100-m-per-pixel Thermal Emission Imaging System data that was subdivided into 140 1.2- by 1.2-km (0.025°) quadrangles and mapped in detail by more than 30 team members. The group map was compiled, consolidated, and iteratively refined into a single GIS project.

13. In addition, minor units of eolian fill and/or bedforms and ejecta blankets adjacent to larger craters are present but are not discussed further.

14. Bradbury Landing refers to the patch of ground where Curiosity touched down on the surface of Mars. It commemorates the noted science fiction writer Raymond Bradbury and was designated by NASA.

18. The morphology of the “bay” is the result of postdepositional erosion, perhaps by eolian processes, as shown by the exposures of stratified rock that record dissection. These are eroded rocks and not, for example, shoreline berms. Therefore, the present-day topography does not reflect that at the time of deposition of those strata.

31. Supplementary materials are available on Science Online.

44. The term “raised ridges” may seem redundant, but the designation “raised” is meant to denote the substantial height of the ridges compared to their width.

54. L. B. Aspler, J. R. Chiarenzelli, B. L. Cousins, Fluvial, lacustrine and volcanic sedimentation in the Angikuni sub-basin, and initiation of ~1.84–1.79 Ga Baker Lake Basin, western
