LSPRAY-V: A Lagrangian Spray Module

M.S. Raju
Vantage Partners, LLC, Brook Park, Ohio
Since its founding, NASA has been dedicated to the advancement of aeronautics and space science. The NASA Scientific and Technical Information (STI) Program plays a key part in helping NASA maintain this important role.

The NASA STI Program operates under the auspices of the Agency Chief Information Officer. It collects, organizes, provides for archiving, and disseminates NASA's STI. The NASA STI Program provides access to the NASA Technical Report Server—Registered (NTRS Reg) and NASA Technical Report Server—Public (NTRS) thus providing one of the largest collections of aeronautical and space science STI in the world. Results are published in both non-NASA channels and by NASA in the NASA STI Report Series, which includes the following report types:

- **TECHNICAL PUBLICATION.** Reports of completed research or a major significant phase of research that present the results of NASA programs and include extensive data or theoretical analysis. Includes compilations of significant scientific and technical data and information deemed to be of continuing reference value. NASA counter-part of peer-reviewed formal professional papers, but has less stringent limitations on manuscript length and extent of graphic presentations.

- **TECHNICAL MEMORANDUM.** Scientific and technical findings that are preliminary or of specialized interest, e.g., “quick-release” reports, working papers, and bibliographies that contain minimal annotation. Does not contain extensive analysis.

- **CONTRACTOR REPORT.** Scientific and technical findings by NASA-sponsored contractors and grantees.

- **CONFERENCE PUBLICATION.** Collected papers from scientific and technical conferences, symposia, seminars, or other meetings sponsored or co-sponsored by NASA.

- **SPECIAL PUBLICATION.** Scientific, technical, or historical information from NASA programs, projects, and missions, often concerned with subjects having substantial public interest.

- **TECHNICAL TRANSLATION.** English-language translations of foreign scientific and technical material pertinent to NASA's mission.

For more information about the NASA STI program, see the following:

- Access the NASA STI program home page at [http://www.sti.nasa.gov](http://www.sti.nasa.gov)
- E-mail your question to help@sti.nasa.gov
- Fax your question to the NASA STI Information Desk at 757-864-6500
- Telephone the NASA STI Information Desk at 757-864-9658

ABSTRACT

LSPRAY-V is a Lagrangian spray solver developed for application with unstructured grids and massively parallel computers. It is mainly designed to predict the flow, thermal and transport properties of a rapidly vaporizing spray encountered over a wide range of operating conditions in modern aircraft engine development. It could easily be coupled with any existing gas-phase flow and/or Monte Carlo Probability Density Function (PDF) solvers. The manual provides the user with an understanding of various models involved in the spray formulation, its code structure and solution algorithm, and various other issues related to parallelization and its coupling with other solvers. With the development of LSPRAY-V, we have advanced the state-of-the-art in spray computations in several important ways.

- It facilitates the use of both structured & unstructured grids and parallel computing and, thereby, facilitates large-scale combustor computations involving complex geometrical configurations. The solver accommodates the use of an unstructured mesh with mixed elements of either triangular, quadrilateral, and/or tetrahedral type.

- In order to deal with modern gas-turbine fuels that are mixtures of many compounds, it takes into account the modeling of multicomponent liquid fuels with variable properties.

- Various well-established vaporization and atomization models are incorporated into our spray code to cover a wide range of engine operating conditions: low to high pressures including supercritical conditions, and superheat conditions associated with flash vaporization. The initial droplet conditions could be prescribed based on either a single-point or multi-point droplet injection. The multi-point injection could be in the form of a line or circular point injection. The initial droplet conditions could be specified entirely in the form of a table based on known experimental data, or some of the initial conditions could be calculated based on several widely-used droplet-size distribution functions or primary atomization models incorporated into our spray code. For low pressures, we have incorporated the following primary atomization models: (a) sheet breakup, (b) air blast, (c) blob jet, or (d) BLS (Boundary-Layer Stripping). We have also incorporated a flash induced atomization model to cover superheat conditions. The secondary droplet breakup following primary atomization could be modeled by one of the following models: (a) Rayleigh-Taylor, (b) TAB (Taylor Analogy Breakup), or (c) ETAB (Enhanced Taylor Analogy Breakup).

- The spray module has a multi-liquid and multi-injector capability.

- Our spray code supports all of the boundary conditions of the national combustion code including particle movement through very complex periodic boundary conditions. Upon impact with the wall, a droplet may shatter, rebound, or stick to the wall depending on the level and conditions of collision impact. We have implemented several droplet-wall interaction models into our spray code to cover a wide range of conditions.

- Our spray code can be used in the calculation of both steady as well as unsteady computations.

- The spray module is designed in such a way so that it could easily be coupled with other CFD codes.
With the aim of improving the overall solution procedure of the national combustion code involving sprays, we have made several other relevant contributions to the gas-side of computations:

- In order to demonstrate the importance of chemistry/turbulence interactions in the modeling of reacting sprays, we have extended the joint scalar Monte Carlo PDF (Probability Density Function) approach to the modeling of spray calculations with unstructured grids, and parallel computing.

- In order to account for non-ideal gas behavior associated with high-pressure conditions, we have completed the implementation of a high-pressure EOS (equation of state). Also, we have implemented several high-pressure corrections that go into the calculation of gas-phase transport properties.

The spray solution procedure provided favorable results when applied to the modeling of various reacting/non-reacting flows encountered in gas-turbine combustors, stratified-charge rotary combustion (Wankel) engines, supersonic and pulse detonation combustion devices. Its use has been demonstrated in various NASA projects: the NASA’s fundamental aeronautics program initiative on emissions through the Supersonics (SUP) and Subsonic Fixed Wing (SFW) project offices, Ultra-Efficient Engine Technology (UEET), Pulse Detonation Combustion Technology (PDCT), & Rotary Combustion Engine Technology Enablement Project (RCETEP).
NOMENCLATURE

\( a \) \, liquid jet radius, m, or parent drop radius, m

\( a_0 \) \, initial droplet radius, m

\( \mathbf{a}_n \) \, outward area normal vector of the nth surface, m

\( A \) \, a constant

\( B_k \) \, Spalding mass transfer number

\( B_t \) \, Spalding heat transfer number

\( B_o \) \, a constant

\( c_{freq} \) \, a constant

\( C \) \, a constant

\( C_D \) \, drag coefficient

\( C_p \) \, specific heat, J/(kg K)

\( D \) \, turbulent diffusion coefficient, m\(^2\)/s

\( D_{AB} \) \, diffusion coefficient, cm\(^2\)/s

\( d \) \, droplet diameter, m

\( d_b \) \, droplet diameter after primary breakup, m

\( d_L \) \, ligament diameter, m

\( d_o \) \, orifice diameter, m

\( d_{parent} \) \, parent drop diameter, m

\( d_{product} \) \, product drop diameter, m

\( dt \) \, time increment, s

\( d\theta \) \, half-cone angle, deg.

\( E_{parent} \) \, energy contained in the parent drop, (kg m\(^2\))/s\(^2\)

\( E_{product} \) \, energy contained in the product drop, (kg m\(^2\))/s\(^2\)

\( h \) \, specific enthalpy, J/kg, liquid sheet thickness, m

\( I_0, I_1 \) \, modified Bessel functions of the first kind

\( k \) \, turbulence kinetic energy, m\(^2\)/s\(^2\), wave number, 1/m, or thermal conductivity, J/(uns K)

\( k_{ij} \) \, binary interaction parameter

\( K_b \) \, a breakup constant, 1/s

\( K_{sb} \) \, wave number associated with sheet breakup, 1/m

\( k_1, k_2 \) \, constants

\( K_{Lb} \) \, wave number associated with ligament breakup, 1/m

\( K_0, K_1 \) \, modified Bessel functions of the second kind

\( l \) \, modified wave number, 1/m

\( l_k \) \, mixture latent heat of evaporation, J/kg

\( l_{k,eff} \) \, effective latent heat of evaporation, J/kg (defined in Eq. (35))

\( l_{kn} \) \, heat of vaporization at normal boiling point, J/kg

\( L \) \, liquid sheet breakup length, m

\( \dot{m} \) \, liquid mass flow rate, kg/s

\( \dot{m}_k \) \, droplet vaporization rate, kg/s

\( \dot{m}_{k,flash} \) \, droplet vaporization rate under flash evaporating conditions, kg/s

\( \dot{m}_{ko} \) \, initial mass flow rate associated with kth droplet group, kg/s

\( \dot{m}_{k,t} \) \, droplet vaporization rate due to heat transfer, kg/s

\( m_o \) \, mass of the parent drop, kg

\( \bar{m}(t) \) \, mean mass of the product drop distribution, kg

\( M \) \, molecular weight, kg/kg-mole

\( M_a \) \, molecular weight of gas excluding fuel species, kg/kg-mole

\( M_f \) \, molecular weight of fuel, kg/kg-mole

\( M_i \) \, molecular weight of ith species, kg/kg-mole

\( M_{shed} \) \, shed drop mass, kg

\( M_{total} \) \, total mass of computational cell

\( M_{total} \) \, total mass of computational cells

\( N \) \, drop number

\( N_o \) \, parent drop number

\( N_f \) \, number of surfaces contained in a given computational cell

\( N_p \) \, total number of computational cells

\( N_{Nu} \) \, Nusselt number

\( P \) \, pressure, N/m\(^2\)

\( P_c \) \, critical pressure, N/m\(^2\)

\( Pr \) \, Prandtl number

\( P_r \) \, reduced pressure, \( P/P_c \)

\( P_{sat} \) \, saturation pressure, N/m\(^2\)

\( Q \) \, density ratio (\( \rho_g/\rho_l \))

\( r \) \, radius (\( \sqrt{a^3/r_{SMR}} \)), m

\( r_k \) \, droplet radius, m

\( r_{ko} \) \, initial droplet radial location, m

\( r_{SMR} \) \, Sauter mean radius, m

\( R_e \) \, Reynolds number

\( RND \) \, random number

\( Sh \) \, Sherwood number

\( s_k \) \, droplet radius-squared (\( = r_k^2 \)), m\(^2\)

\( s_{mlc} \) \, source term contribution from liquid exchange to mass conservation, kg/s

\( s_{mlc} \) \, source term contribution from liquid exchange to energy conservation, J/s

\( s_{mlm} \) \, source term contribution from liquid exchange to momentum conservation, kg m/s\(^2\)
source term contribution from liquid exchange to species conservation, kg/s
SMD Sauter mean diameter, m
t time, s
td non-dimensional time (\(=\frac{2\rho \alpha^2}{\mu t}\))
T temperature, K, or non-dimensional number (\(=ZW\epsilon_t^{0.5}\))
\(T_b\) boiling temperature, K
\(T_{nb}\) normal boiling temperature, K
\(T_c\) critical temperature, K
\(T_k\) kth droplet temperature, K
\(T_r\) reduced temperature, \(T/T_c\)
\(u_d\) drop deceleration, m/s
\(u_i\) ith velocity component, m/s
\(u_{ik}\) ith velocity component of kth droplet group, m/s
\(U\) relative velocity between gas and liquid, m/s, or relative drop velocity, m/s
\(v_p\) product drop velocity component, m/s
\(V\) initial liquid velocity, m/s
\(V_c\) volume of the computational cell, m³, or critical molar volume, m³/kg-mole
\(V_n\) molar volume at normal pressure, m³/kg-mole
\(\text{We}\) Weber number (\(=\frac{\rho T U^2}{\sigma}\))
\(\dot{\omega}_j\) gas-phase chemical reaction rate, 1/s
\(x_i\) Cartesian coordinate in the ith direction, m
\(x\) Cartesian coordinate, m, or drop deformation distance, m
\(\chi\) mole fraction
\(\delta\) Dirac-delta function, or initial liquid sheet thickness, m
\(\Delta p\) pressure drop in the injector, N/m²
\(\Delta t_f\) local time step used in the flow solver, s
\(\Delta t_{gl}\) global time step used in the spray solver, s
\(\Delta t_{il}\) fuel injection time step, s
\(\Delta t_{ml}\) allowable time step in the spray solver, s
\(\Delta V\) computational cell volume, m³
\(\epsilon\) rate of turbulence dissipation, m²/s³
\(\epsilon_j\) fractional mass evaporating rate of species at the droplet surface
\(\eta\) wave amplitude, m
\(\Gamma_\phi\) turbulent diffusion coefficient, kg/ms, or a factor (\(=-210\left[\frac{1}{T_c M^3}\right]^{1/6}\))
\(\lambda\) thermal conductivity, J/(ms K), or wavelength, m
\(\Lambda\) wavelength associated with \(\Omega\), or wavelength associated with Rayleigh-Taylor breakup, m
\(\mu\) dynamic viscosity, kg/ms
\(\nu\) kinematic viscosity, m²/s
\(\omega\) turbulence frequency, 1/s,
\(\Omega\) maximum growth rate, 1/s
\(\rho\) density, kg/m³
\(\rho_{in}\) liquid density (at 1 bar, 273.15 K), kg/m³
\(\rho_r\) reduced density (\(=\rho/\rho_c\))
\(\sigma\) potential length constant, Angstrom (\(=0.1\) nm), surface tension, kg/s², or characteristic diameter of a molecule in Table 1
\(\tau\) characteristic breakup time (\(=1/K_\beta\)), s
\(\theta\) void fraction, or spray cone angle, deg.

1 INTRODUCTION

There are many occurrences of sprays in a variety of industrial and power applications and materials processing [1]. A liquid spray is a two phase flow with the gas as the continuous phase and the liquid as the dispersed phase in the form of droplets or ligaments [1]. The coupling between the two phases occurs through the exchanges of mass, momentum, and energy involving a wide range of thermal, mass, and fluid dynamic factors. A number of finite-difference formulations have been advanced over the years for predicting the flow (mass and momentum) and thermal properties of a rapidly vaporizing spray. Some of the pros and cons of various formulations can be found in [1-5].

The state of the art in multi-dimensional combustor modeling, as evidenced by the level of sophistication employed in terms of modeling and numerical accuracy considerations, is also dictated by the available computer memory and turnaround times afforded by present-day computers. With the aim of advancing the current multi-dimensional computational tools used in the design of advanced technology combustors, a solution procedure is developed that combines the novelty of the coupled CFD/spray/scalar Monte Carlo PDF (Probability Density Function) computations on unstructured grids with the ability to run on parallel architectures. In this approach, the mean gas-phase velocity and turbulence fields are determined from the solution of a conventional CFD method, the scalar fields of species and enthalpy from a modeled PDF transport equation using a Monte Carlo method, and a Lagrangian-based dilute spray model is used for the liquid-phase representation.

The gas-turbine combustor flows are often characterized by a complex interaction between various rate-controlling processes associated with turbulent transport, mixing, chemical kinetics, evaporation and spreading rates of spray, convective and radiative heat transfer, among others [10]. The phenomena to be modeled as controlled by these processes often interact with each other at various disparate time and length scales. In particular, turbulence plays an important role in determining the rates of mass and heat transfer, chemical reactions, and liquid-phase evaporation in many practical combustion devices. The influence of turbulence in a diffusion flame manifests itself in several forms, ranging from the so-called wrinkled or stretched flamelets regime to the distributed combustion regime, depending upon how turbulence interacts with various flame scales [69-70].

Most of the turbulence closure models for reactive flows have difficulty in treating nonlinear reaction rates [69-70]. The use of assumed shape PDF methods was found to provide reasonable predictions of pattern factors and NOX emissions at the combustor exit [71]. However, their extension to multi-scalar chemistry becomes quite intractable. The solution procedure based on the modeled joint-composition PDF transport equation has an advantage in that it treats the nonlinear reaction rates without any approximation. This approach holds the promise of modeling various important combustion phenomena relevant to practical combustion devices such as flame extinction and blow-off limits, and unburnt hydrocarbons (UHC), CO, and NOX predictions [71].

With the aim of demonstrating the viability of the PDF approach to the modeling of practical combustion flows, we have undertaken the task of extending this technique to the modeling of sprays as a part of the NCC (National Combustion Code) development program [7-15]. In order to facilitate large-scale combustor computations, we have extended our previous work on the combined CFD/spray/PDF computations to parallel computing [10-15]. The use of parallel computing offers enormous computational power and memory as it can make use of hundreds of processors in concert to solve a complex problem. The trend towards parallel computing is driven by two major developments: the widespread use of distributed computing and the recent advancements in MPPs (Massively Parallel Processors). The solver is designed to be massively parallel and automatically scales with the number of available processors. A current status of the use of the parallel computing in turbulent reacting flows involving sprays, scalar Monte Carlo PDF, and unstructured grids was described in Ref. [11]. It outlined several numerical techniques developed for overcoming some of the high computer CPU-time and memory-storage requirements associated with the use of Monte Carlo solution methods. The parallel performance of both the PDF and CFD modules was found to be excellent but the results were mixed for the spray computations showing reasonable performance on massively parallel computers like Cray T3D; but its performance was poor on the workstation clusters [10]. In order to improve the parallel performance of the spray module, two different domain decomposition strategies were developed and the results from both strategies were summarized.
the vaporization models of a polydisperse spray take on various well-established models for droplet drag; ical diffusion. The liquid-phase formulation is chosen as it reduces the errors associated with numer-
a Lagrangian representation. A Lagrangian scheme is they could be solved by means of either an Eulerian or an Eulerian Monte Carlo PDF solver [15], we were able to demonstrate the use of the joint scalar Monte Carlo PDF method in the modeling of complex multidimensional reacting flows (e.g., gas-turbine combustor flows) [10-15]. In this manual, we only concentrate on providing the details of our spray module. However, further details on the application of the joint scalar Monte Carlo PDF method to two-phase flows could be found elsewhere in [10-13, 15].

In this manual, we summarize some important aspects of our spray formulation without making any attempt to provide an in-depth review on the fluid dynamic and transport behavior of reacting sprays [6-15]. Depending on the nature of the spray, an appropriate selection could be made from the choice of various well-known spray formulations (multicontinuina, discrete-particle, or probabilistic) based on either a Lagrangian or an Eulerian representation for the liquid-phase equations by making use of appropriate droplet sub-grid models. The present solution procedure could be used within the context of both multicontinua and probabilistic spray formulations, as it allows for resolution on a scale greater than the average spacing between two neighboring droplets [1]. For NCC, the adopted choice for the gas phase was an Eulerian scheme. The liquid-phase equations form a system of hyperbolic equations and they could be solved by means of either an Eulerian or a Lagrangian representation. A Lagrangian scheme is chosen as it reduces the errors associated with numerical diffusion. The liquid-phase formulation is based on various well-established models for droplet drag; the vaporization models of a polydisperse spray take into account the transient effects associated with the droplet internal heating and the forced convection effects associated with droplet internal circulation; and it employs models for gas-film valid over a wide range of low to intermediate droplet Reynolds numbers [7]. Our current formulation is applicable for flows with a dilute spray approximation where the droplet loading is low. The numerical method could be used within the context of both steady and unsteady calculations [8-13]. Not considered in the present release of the code are the effects associated with droplet/shock inter-

Currently, most of the finite-difference techniques used for predicting the two-phase flows make use of the physics derived from single-component liquid droplet studies with constant properties. However, it is well known that most of the gas-turbine fuels are multicomponent mixtures of many compounds with a wide distillation curve [7, 18]. The multicomponent nature of the liquid sprays is becoming evident with the increasing need to use jet fuels derived from heavier petroleum compounds. The gasifica-
tion behavior of a multicomponent fuel droplet may differ significantly over that of a pure single compo-
ent fuel droplet [18]. Also, the calculation of the variable thermo-transport properties of the liquid-
mixtures becomes more important at high pressures. The flame ignition characteristics (such as the phe-
nomena associated with flame blow-off and extinction conditions) could also be influenced by the nonuni-
form concentration of the fuels with different volatilities. However, the importance of the multicomponent liquid fuels with variable properties received little at-
tention in the modeling of comprehensive gas-turbine combustor spray computations. With this in mind, we have extended the spray formulation to multicom-
ponent liquid sprays in order to deal with the gas-
turbine fuels that are mixtures of many compounds. This implementation also takes into account the ef-
effect of variable liquid properties.

In order to reduce some uncertainty associated with the specification of initial droplet conditions, we have undertaken the task of integrating an at-
omization module into our spray solution procedure. The atomization module was developed by CFDRC Inc. [47] in collaboration with the university of Wis-
cconsin (UW) [45-46]. Our computational experience with the assessment of various atomization models was summarized in [59-60, 78]. A complete descrip-
tion of all the primary atomization as well as the secondary droplet breakup models contained in the
CFDRC/UW atomization module is provided in the appendix.

An understanding of droplet behavior under superheat conditions is identified to be a topic of importance in the design of modern supersonic engines, scramjet, and ramjet afterburners [61-64, & 74]. It is because (1) higher heat-load requirements may lead to the use of the same fuel as a coolant, (2) under some engine operating conditions the nozzles are required to operate under low backpressures, and (3) under normal gas-turbine operating conditions, it is estimated that a small fraction of the liquid fuel may be released by flash boiling [62]. There are some reported incidences of engine damage due to flash atomization in gasoline direct-injection internal combustion engines [62]. Because of its importance in some NASA-supported future engine development projects, we have undertaken an assessment study to establish the baseline accuracy of various existing vaporization and atomization models used in the calculation of a superheated spray. As a part of this effort, we have incorporated a solution procedure based on the modeling approach developed by [62-64, & 74]. Our computational experience with the assessment of this modeling approach is summarized in [78-79].

There is a need to understand the droplet behavior under supercritical pressures as some modern gas-turbine combustors tend to operate under increasingly high pressures [19-20, & 81-86]. Based on some important aspects of the modeling approach derived from [20, & 83-86], we have implemented a high-pressure droplet vaporization model into our spray code. As a part of this effort, we have also implemented the Peng-Robinson equation of state following the approach of [16-17, & 28], the high-pressure corrections to the gas-phase transport properties from [16, 19, & 29-31], and the high-pressure corrections to the liquid-phase transport properties from [16-18].

One important aspect of spray modeling is how to deal with the collision dynamics of a droplet impact with the wall. Upon its impact with the wall, a droplet may shatter, rebound, or stick to the wall. In order to deal with several possible outcomes, we have incorporated the modeling approach of [80-81] based on the coding partially received from CFDRC.

Some other important aspects of the spray module are summarized below:

- An efficient particle tracking algorithm was developed and implemented into the Lagrangian spray solver in order to facilitate particle movement in an unstructured grid of mixed elements.
- LSPRAY-V is currently coupled with an unstructured flow (CFD) solver of NCC [21-23], and an Eulerian-based Monte Carlo probability density function solver - EUPDF [15], which were selected to be as the integral components of the NCC cluster of modules. EUPDF provides the solution for the scalar fields of species and enthalpy from a modeled PDF transport equation using a Monte Carlo method.
- The spray solver receives the mean velocity and turbulence fields from the flow solver. The solution for the scalar (energy and species) fields could be provided by means of either a conventional CFD solver or a Monte Carlo PDF solver depending on the choice of the solver.
- The spray solver supplies the spray source-term contributions arising from the exchanges of mass, momentum and energy with the liquid-phase to the flow solvers (CFD and/or Monte Carlo PDF). This information could be used in either conservative or non-conservative finite-difference formulations of the gas phase equations.

The furnished code demonstrates the successful methods used for parallelization and coupling of the spray to the flow code. First, complete details of the spray solution procedure is presented along with several other numerical issues related to the coupling between the CFD, LSPRAY-V, and EUPDF solvers. It is followed by a brief description of the combined parallel performance of the three solvers (CFD, EUPDF, and LSPRAY-V) along with a brief summary of the validation cases.

## 2 GOVERNING EQUATIONS FOR GAS PHASE

Here, we summarize the governing gas-phase conservation equations in Eulerian coordinates [1]. This is done for the purpose of identifying the interphase source terms arising from the exchanges of mass, momentum, and energy with the liquid phase. They are valid for a dilute spray with a void fraction of the gas, \( \theta \), close to unity. The void fraction is defined as the ratio of the equivalent volume of gas to a given volume of a gas and liquid mixture.

The conservation of the mass leads to:
\[ [\bar{\rho} V_c],_t + [\bar{\rho} V_c u_i],_x = s_{mls} = \sum_k n_k \dot{m}_k \]  

(1)

The source term is given as a summation over different classes of droplets. Each class represents the average properties of a different polydisperse group of droplets. Here, \( n_k \) represents the number of droplets in a given class and \( \dot{m}_k \) represents the corresponding mass vaporization rate.

For the conservation of the \( j \)th species, we have:

\[ [\bar{\rho} V_c y_j],_t + [\bar{\rho} V_c u_i y_j],_x - [\bar{\rho} V_c D y_j],_x + \bar{\rho} V_c \dot{w}_j = s_{mls} = \sum_k \epsilon_j n_k \dot{m}_k \]  

(2)

where

\[ \sum_j \dot{w}_j = 0 \text{ and } \sum_j \epsilon_j = 1 \]

For the species conservation, the source term contains an additional variable, \( \epsilon_j \), which is defined as the fractional vaporization rate for species \( j \).

For the momentum conservation, we have:

\[ [\bar{\rho} V_c u_i],_t + [\bar{\rho} V_c u_i u_j],_x + [\bar{\rho} V_c],_x - \theta [V_c \tau_{ij}],_x - [(1 - \theta)V_c \tau_{ij}],_x = s_{mlm} = \sum_k n_k \dot{m}_k u_{ki,t} - \sum_k \frac{4\pi}{3} \rho_k r_k^3 n_k u_{ki,t} \]  

(3)

where the shear stress \( \tau_{ij} \) in Eq. (3) is given by:

\[ \tau_{ij} = \mu [u_i, x_j + u_j, x_i] - \frac{2}{3} \mu \delta_{ij} u_i, x_i \]

For the momentum conservation, the first source term represents the momentum associated with liquid fuel vapor and the second represents the momentum change associated with droplet drag.

For the energy conservation, we have:

\[ [\bar{\rho} V_c h],_t + [\bar{\rho} V_c u_i h],_x - [\theta V_c \lambda T],_x = \sum_k n_k \dot{m}_k \left( \dot{h}_s - l_{k, eff} \right) \]  

(4)

Similarly, the energy conservation has a source term contribution from the added liquid fuel vapor and an additional contribution associated with the effective latent heat of vaporization which accounts for the heat flux (loss or gain) to the droplet interior from the ambient.

The main purpose of the spray solver is to calculate the source terms arising from the exchanges of the mass, momentum, and energy. In the case of NCC, it provides the calculated source terms to both the CFD and Monte Carlo PDF solvers.

### 3 HIGH PRESSURE EQUATION OF STATE

In order to calculate the high pressure gas behavior, the Peng-Robinson EOS (Equation-Of-State) is employed for a multi-component mixture in the following form [16-17,28]:

\[ P = \frac{RT}{V - b_m} - \frac{a_m}{V^2 + 2b_m V - b_m^2} \]

(5)

where

\[ a_m = \sum_i \sum_j y_i y_j (a_i a_j)^{1/2} (1 - k_{ij}), \]

\[ b_m = \sum_i y_i b_i, \]

\[ b_i = \frac{0.07780 R T_{m_i}}{T_{m_i}}, \]

\[ a_i = \frac{0.45724 R^2 T_{m_i}^2}{P_{m_i}} [1 + f_{iw} (1 - T_{ir}^{1/2})]^{2}, \]

\[ T_{ir} = T / T_{ic} , \]

\[ f_{iw} = 0.37464 + 1.54226 \omega_i - 0.26992 \omega_i^2, \]

\( \omega_i \) is known as the acentric factor of the molecules which is a measure of non-sphericity of the molecules, and \( k_{ij} \) is known as the binary interaction coefficient. However, the Peng-Robinson EOS is rewritten as a cubic EOS in terms of the compressibility factor, \( Z (= \frac{P}{\rho T}) \), before it is solved:

\[ Z^3 - (1 - B^*) Z^2 + (A^* - 2B^* - 3B^{*2}) Z - A^* B^* - B^* + B^{*3} = 0 \]

(6)

where

\[ A^* = \frac{a_m P}{\rho T^2}, \text{ and } B^* = \frac{b_m P}{\rho T}. \]

</table>
We have chosen the Peng-Robinson EOS because of its simplicity and, more importantly, it proved to be very useful in the supercritical droplet vaporization studies of [19-20].

Table 1 lists various physical constants for some of the species that we found to be of interest in our spray computations. It contains values for the boiling temperature at normal pressure, the critical temperature, the critical pressure, the critical density, the latent heat of vaporization at normal pressure, the critical molar volume, the molar volume at normal pressure, and the acentric factor of the molecules. Most of this data is collected from [16-18] and is useful in both the evaluation of the Peng-Robinson EOS and the calculation of various other variable properties. And Table 2 lists the binary interaction parameters, $k_{ij}$, used in a calculation for the multi-component mixture of n-heptane, $O_2$, $N_2$, CO$_2$, & $H_2O$. While the data for most of the binary pairs was obtained from various reference books, some of the missing data, however, is replaced with known data found for other binary pairs of molecules with similar molecular weights.

4 HIGH PRESSURE CORRECTIONS FOR GAS-PHASE TRANSPORT PROPERTIES

The effect of pressure on the viscosity of pure gases is determined by making use of the Reichenberg method [16,19,29]:

$$\frac{\mu}{\mu_n} = 1 + Q_v \frac{A_v B_r^{3/2}}{B_i P_r + (1 + C_v P_r^{1/3})^{-1}}$$

where

$$A_v = \frac{\alpha_2}{\rho_r} exp(\alpha_2 T_r^\gamma) \quad B_v = A_v (\beta_1 T_r - \beta_2)$$
$$C_v = \frac{\gamma_1}{\rho_r} exp(\gamma_1 T_r) \quad D_v = \frac{\lambda_1}{\rho_r} exp(\lambda_1 T_r^\gamma)$$

$$\alpha_1 = 1.982510^{-03} \quad \alpha_2 = 5.2683 \quad a = -0.5767$$
$$\beta_1 = 1.6552 \quad \beta_2 = 1.2760$$
$$\gamma_1 = 0.1319 \quad \gamma_2 = 3.7035 \quad c = -79.8678$$
$$\lambda_1 = 2.9496 \quad \lambda_2 = 2.9190 \quad d = -16.6169$$

and $Q_v = 1.0$ for non-polar molecules.

The effect of pressure on the thermal conductivity of pure gases is determined by making use of the Stiel & Thodos method [16,19,30]:

$$(\lambda - \lambda_n) Z_c^5 = 1.2210^{-2}[exp(0.535 \rho_r) - 1]$$
when $\rho_r < 0.5$

$$(\lambda - \lambda_n) Z_c^5 = 1.1410^{-2}[exp(0.67 \rho_r) - 1.069]$$
when $0.5 < \rho_r < 2.0$

$$(\lambda - \lambda_n) Z_c^5 = 2.6010^{-2}[exp(1.155 \rho_r) + 2.016]$$
when $2.0 < \rho_r < 2.8$

where $\lambda$ is in W/(m.K), $\Gamma = 210 [T_r \rho_r^{3/2}]^{1/6}$, $Z_c$ is the critical compressibility, and $\rho_r$ is the reduced density $\rho/\rho_c = V_c/V$.

The effect of pressure & temperature on diffusion coefficients in gases is determined by making use of Takahashi correlation [16,19,31]:

$$\frac{D_{AB} P}{(D_{AB} P)^+} = f(T_r, P_r)$$

where $D_{AB} =$ diffusion coefficient, cm$^2$/s, $P =$ pressure, bar, the superscript + indicates that low-pressure values are to be used, and the reduced pressure and temperature in the above equation are calculated as follows:

$$T_r = \frac{T}{T_{cAB}} \quad T_{cAB} = y_A T_{cA} + y_B T_{cB}$$
$$P_r = \frac{P}{P_{cAB}} \quad P_{cAB} = y_A P_{cA} + y_B P_{cB}$$

This correlation is valid for a system involving a trace solute diffusing in a supercritical fluid. It is shown to provide satisfactory results but it is based on a very limited set of available experimental data. The graphical representation of the Takahashi function is given in Fig. 1.

It is noteworthy that at low pressures, the polynomial fits for the variable thermodynamic properties are taken from the data set compiled by McBride et al [24]. The transport properties involving the thermal conductivity and molecular viscosity for individual species is estimated based on the Chapman-Enskog collision theory [25-27]. And Wilke’s formulae is used to determine the properties of mixture [25-27]. The binary-diffusion coefficients are determined based on the Chapman-Enskog theory and the Lennard-Jones potential [25-27].
5 LIQUID-PHASE EQUATIONS

Figure 1 Takahashi correlation showing the variation of the binary diffusion coefficient versus reduced pressure at different reduced temperatures.

Here, we summarize the governing equations for the liquid-phase based on a Lagrangian formulation where the equations for particle position and velocity are described by a set of ordinary differential equations. For the particle position of the kth droplet group, we have:

\[
\frac{dx_{ik}}{dt} = u_{ik} \tag{12}
\]

For the droplet velocity:

\[
\frac{du_{ik}}{dt} = \frac{3}{16} \frac{C_D \rho_g \rho_k r_k^2}{\rho_k r_k^2} \left[ u_g + u'_g - u_{ik} \right] \tag{13}
\]

where

\[
C_D = \frac{24}{Re_k} \left( 1 + \frac{Re_k^{2/3}}{6} \right) \tag{14}
\]

According to Yuen and Chen [32], the droplet drag for a vaporizing droplet could be calculated by a solid-sphere drag correlation but suggested using a correction in the evaluation of the droplet Reynolds number for the average viscosity based on a 1/3 weighting rule as given by Eq. (46). The droplet Reynolds number is given by:

\[
Re_k = \frac{r_k \rho_g}{\mu_g} \left[ (u_g + u'_g - u_k), (u_g + u'_g - u_k) \right]^{1/2} \tag{15}
\]

By following the approach taken from KIVA [33], a gas turbulence velocity, \( u'_g \), is added to the local mean gas velocity when calculating the droplet drag and vaporization rates. The gas velocity fluctuations is calculated by randomly sampling a Gaussian distribution with mean square deviation, \( 2/3k \). The Gaussian is given by

\[
G(u'_g) = (4/3 \pi k)^{-3/2} exp[-3|u'_g|^2/4k] \tag{16}
\]

The gas fluctuating component is calculated once at every turbulence interaction time, \( t_{tur} \), and is otherwise held constant [33]. The correlation time is taken to be the minimum of either the eddy time or the transit time taken by the droplet to traverse the eddy. It is given by

\[
t_{tur} = \min \left( \frac{k}{c_t}, \frac{k^{3/2}}{\epsilon} \frac{1}{|u_g + u'_g - u_k|} \right) \tag{17}
\]

where \( c_t \) is an empirical constant with a value of 0.16432.

The liquid mixture density, \( \rho_k \), in Eq. (13) is given by [16,18]:

\[
\rho_k = \sum_i y_{ki} \rho_{ki} \tag{18}
\]

and the individual component liquid density is given by:

\[
\rho_{ki} = \frac{M_{ki}}{V_{ki}} \tag{19}
\]

where the molar volume, \( V_{ki} \), is

\[
V_{ki} = V_{ci}(0.29056 - 0.8775 \omega_i) c_v \tag{20}
\]

and

\[
c_v = \left[ 1 - \frac{T_k}{T_{ci}} \right] \frac{2}{h}
\]

The droplet regression rate is determined from one of three different correlations depending upon the droplet Reynolds number range. The first correlation as given by Eq. (21) is based on a gas-film analysis developed by Tong & Sirignano [34]. It is based on a combination of stagnation and flat-plate boundary-layer analysis and is valid for Reynolds numbers in the intermediate range. The last two correlations as
given by Eqs. (22) & (23) are taken from Clift et al [35] and are valid when \( Re_k \leq 20 \). In fact, when the droplet Reynolds number goes to zero, Eq. (23) becomes identical to the droplet regression rate of a vaporizing droplet in a quiescent medium [27].

\[
\frac{ds_k}{dt} = -2 \frac{\rho_g D_g}{\rho_k} \left[ \frac{2}{\pi Re_k} \right]^{1/2} f(B_k) \quad \text{if} \quad Re_k > 20
\]

\[
\frac{ds_k}{dt} = -\frac{\rho_g D_g}{\rho_k} \left[ 1 + (1 + Re_k)^{1/3} \right] Re_k^{0.077} \ln(1 + B_k) \quad \text{if} \quad 1 < Re_k \leq 20
\]

\[
\frac{ds_k}{dt} = -\frac{\rho_g D_g}{\rho_k} \left[ 1 + (1 + Re_k)^{1/3} \right] \ln(1 + B_k) \quad \text{if} \quad Re_k < 1
\]

where \( B_k \) is the Spalding mass transfer number and is given by:

\[
B_k = \frac{(y_{fs} - y_f)}{(1 - y_{fs})}
\]

and \( y_{fs} \) is given as a summation over the fuel-species mass fractions at the droplet interface:

\[
y_{fs} = \sum_i y_{is}
\]

and \( y_f \) is given as a summation over the fuel-species mass fractions in the ambient:

\[
y_f = \sum_i y_{fi}
\]

and the function \( f(B_k) \) is similar to that of a Blassius function [1, 36] and is obtained from an analysis similar to that of Emmon’s boundary-layer flow over a flat plate with blowing [36]. The range of validity of this function was extended in Raju and Sirignano [7] to consider the effects associated with a boundary-layer flow with suction.

The internal droplet temperature is determined based on a vortex model [34]. The governing equation for the internal droplet temperature is given by:

\[
\frac{\partial T_k}{\partial t} = \frac{17 \lambda_l}{C_{pl \rho_l r_k}} \left[ \alpha \frac{\partial^2 T_k}{\partial \alpha^2} + (1 + C(t)\alpha) \frac{\partial T_k}{\partial \alpha} \right]
\]

where

\[
C(t) = \frac{3}{17} \left[ \frac{C_{pl \rho_l}}{\lambda_l} \right] r_k \frac{dr_k}{dt}
\]

where \( \alpha \) represents the coordinate normal to the stream-surface of a Hill’s Vortex in the circulating fluid, and \( C(t) \) represents a nondimensional form of the droplet regression rate. The initial and boundary conditions for Eq. (27) are given by:

\[
t = t_{injection}, \quad T_k = T_{k,0}
\]

\[
\alpha = 0, \quad \frac{\partial T_k}{\partial \alpha} = 1 \frac{1}{17} \left[ \frac{C_{pl \rho_l}}{\lambda_l} \right] r_k \frac{dr_k}{dt}
\]

\[
\alpha = 1, \quad \frac{\partial T_k}{\partial \alpha} = -\frac{3 \rho_k}{32 \lambda_l} |k_{k,eff} - l_k| \frac{ds_k}{dt}
\]

where \( \alpha = 0 \) refers to the vortex center, and \( \alpha = 1 \) refers to the droplet surface, and the mixture latent heat of vaporization, \( l_k \), is given by

\[
l_k = \sum_i \epsilon_i l_{ki}
\]

and the individual component latent heat of vaporization, \( l_{ki} \), is given by [16,18]:

\[
l_{ki} = l_{k,li} \left( \frac{T_{ci} - T_k}{T_{ci} - T_{bi}} \right)^{0.38}
\]

and the droplet boiling temperature is given by

\[
T_{bi} = \frac{l_{k,li} M_i / R_a}{l_{k,li} M_i / (R_a t_{min}) - \ln(P)}
\]

and, finally, the effective latent heat of vaporization, \( l_{k,eff} \), is defined as:

\[
l_{k,eff} = l_k + 4\pi \frac{\lambda_l r_k^2}{m_k} \left( \frac{\partial T_k}{\partial r} \right)_s
\]

It is a very useful parameter as it represents the total energy loss associated with the latent heat of vaporization in addition to the heat loss to the droplet interior. \( l_{k,eff} \) is calculated by means of the following relationship [18]:

\[
l_{k,eff} = \frac{C_p (T_g - T_{ks})}{(1 + B_k)^{1/Le} - 1}
\]
Similar to the internal thermal transport, the internal mass transport of a multi-component fuel is given by:

$$\frac{\partial y_{ki}}{\partial t} = 17 \frac{D_k}{r_k^2} \left[ a \frac{\partial^2 y_{ki}}{\partial \alpha^2} + (1 + C(t)\alpha) \frac{\partial y_{ki}}{\partial \alpha} \right]$$  \hspace{1cm} (37)

The initial and boundary conditions for Eq. (37) are given by:

$$t = t_{injection}, \quad y_{ki} = y_{ki,o}$$ \hspace{1cm} (38)

$$\alpha = 0, \quad \frac{\partial y_{ki}}{\partial \alpha} = \frac{1}{17} \left[ \frac{r_k^2}{D_k} \right] \frac{\partial y_{ki}}{\partial t}$$ \hspace{1cm} (39)

$$\alpha = 1, \quad \frac{\partial y_{ki}}{\partial \alpha} = -\frac{3}{32} \frac{1}{D_k} [y_{ki,s} - \epsilon_i \frac{ds_k}{dt}]$$ \hspace{1cm} (40)

By knowing the mass fractions of the liquid species at the droplet surface, the corresponding mole fractions are determined by

$$x_{iks} = \frac{y_{iks}/M_i}{\sum y_{iks}/M_i}$$ \hspace{1cm} (41)

At the droplet interface, the mole fractions of the gas species are obtained by means of Raoult's law:

$$x_{is} = \frac{1}{P} x_{iks} P_{is}$$ \hspace{1cm} (42)

where the partial pressure, $P_{is}$, is determined by means of the Clausius-Clapeyron relationship:

$$P_{is} = \exp \left[ \frac{l_{ki}}{R_u} \left( \frac{1}{T_{is}} - \frac{1}{T_{ks}} \right) \right]$$ \hspace{1cm} (43)

Then, the corresponding mass fractions in the gas phase at the droplet interface are given by

$$y_{is} = \frac{x_{is} M_i}{M_0 (1 - \sum x_{is}) + \sum M_i x_{is}}$$ \hspace{1cm} (44)

where $M_0$ is the molecular weight of the gas excluding fuel vapor. And the fractional mass vaporization rate of liquid species, $\epsilon_i$, is given by

$$\epsilon_i = y_{is} + (1 - y_{fs}) \frac{y_{is} - y_{fs}}{y_f - y_{fs}}$$ \hspace{1cm} (45)

It is noteworthy that the thermodynamic and transport properties at the gas film are calculated at the temperature and composition as determined by the following one-third rule:

$$\phi_{avg} = \frac{1}{3} \phi_g + \frac{2}{3} \phi_{ks}$$ \hspace{1cm} (46)

The correlations for the gas-phase thermodynamic and transport properties are described in Section 4. In a similar way, the liquid-phase thermodynamic and transport properties are determined based on the correlations described in the next section.

6 LOW PRESSURE LIQUID THERMODYNAMIC & TRANSPORT PROPERTIES

The specific heat at constant pressure, $C_{pl}$, thermal conductivity, $\lambda_l$, and viscosity, $\mu_l$, are evaluated by means of the following expressions:

$$C_{pl} = C_{p0} + C_{p1} T + C_{p2} T^2 + C_{p3} T^3 + C_{p4} T^4$$ \hspace{1cm} (47)

$$\lambda_l = \lambda_{l0} + \lambda_{l1} T + \lambda_{l2} T^2 + \lambda_{l3} T^3 + \lambda_{l4} T^4 + \lambda_{l5} T^5$$ \hspace{1cm} (48)

$$\ln \mu_l = \mu_{l0} + \mu_{l1} T + \mu_{l2} T + \mu_{l3} T^2$$ \hspace{1cm} (49)

where $C_{pl}$ is in J/(kg K), $\mu_l$ in (µPa s), and $\lambda_l$ in (W/m K).

Tables 3-5 provide the polynomial constants used in Eqs. (47)-(49) for some of the species that we found to be of interest in our spray computations. Table 3 provides the constants for the liquid specific heat, $C_{pl}$, Table 4 for the liquid thermal conductivity, $\lambda_l$, and Table 5 for the liquid molecular viscosity, $\mu_l$. These tables are compiled with the data taken mostly from the references of [16,18].

The binary diffusion coefficient, $D_{ij}$, is evaluated as follows [16]:

$$D_{ij} = \frac{K_{dif} T}{\mu_j V_j^{1/3}}$$ \hspace{1cm} (50)

where $K_{dif} = 8.210^{-8}(1 + \frac{3V_j}{V_i})^{2/3}$). One should be careful in using this approximation as it is based on a scarce set of available experimental data.

The specific heat for a multicomponent mixture is given by:

$$C_{pm} = \sum_{i=1}^{n} y_i C_{pi}$$ \hspace{1cm} (51)
Table 3. Polynomial constants for liquid specific heat.

And the thermal conductivity of a multi-component mixture is calculated by means of the Li method [16].

\[ \lambda_m = \sum_{i=1}^{n} \sum_{j=1}^{n} \phi_i \phi_j \lambda_{ij} \]  

(52)

where

\[ \lambda_{ij} = 2(\lambda_i^{-1} + \lambda_j^{-1})^{-1} \]

\[ \phi_i = \frac{x_i V_i}{\sum_{j=1}^{n} x_j V_j} \]

where \( x_i \) is the mole fraction of the species \( i \), \( \phi_i \) is a volume fraction of the \( i \)th species, and \( V_i \) is the molar volume of the pure fluid.

7 HIGH-PRESSURE LIQUID TRANSPORT PROPERTIES

The high-pressure correction for thermal conductivity is calculated by means of a correlation taken from Refs. [16-18].

\[ W_{\lambda} = 1.0 + \left( \frac{P_r}{31.6 + T_r^2(1.0 - \exp(-0.2P_r))} \right) Q_{\lambda}, \quad P_r < 12.0 \]  

(53)

\[ W_{\lambda} = 1.0 + \left( \frac{P_r^{0.67}}{0.0667 + 0.1597T_r^2} \right) Q_{\lambda}, \quad P_r > 12.0 \]  

(54)

where \( Q_{\lambda} = 8.6514 - 3.78T_r - T_r^2 \).

The high pressure correction for viscosity is also calculated by means of a correlation taken from Refs. [16-18].

\[ W_{\mu} = (1.0 + B_\mu (0.47214 \Delta P_r) A_\mu )/(1.0 + C_\mu \omega \Delta P_r) \]  

(55)

where

\[ \Delta P_r = \frac{(P - P_{sat})}{P_r} \]

\[ A_\mu = 0.9999 - 4.424E - 04/(T_r^{0.03877} - 0.999) \]

\[ B_\mu = 0.3257 / (1.0039 - T_r^{0.577} 
\]

\[ C_\mu = -0.0792 + 2.1616T_r - 13.404T_r^2 + 44.1706T_r^3 - 84.829T_r^4 + 96.1209T_r^5 - 59.8127T_r^6 + 15.6719T_r^7 \]

It is noteworthy that in calculating the properties of a multi-component mixture that we have adopted the same kind of mixing rules as described in the previous section.

8 VAPORIZATION MODELING OF A SUPERHEATED DROPLET

Flashin phenomena refers to a process that is in thermodynamic non-equilibrium when a liquid is superheated [72-73]. The reasons for its occurrence are mainly two-fold [72-73]: (1) a liquid fuel can be heated to a temperature above its saturation temperature, and (2) when a liquid is depressurized rapidly it can lead to flashing as the thermal inertia tends to maintain its bulk internal temperature above the saturation temperature. Although flash evaporation is considered to be detrimental to engine performance under normal circumstances, it can have some potential benefits. It is known to produce a fine spray with enhanced atomization, increase effective spray cone angle, and decrease spray penetration [61].

An understanding of flash injection is of importance in some applications involving scramjet and ramjet afterburners because the same liquid fuel is often used as a coolant. Also, the engine conditions are such that nozzles operate at low back pressures with supersonic outflow [61]. The objective of our work is to establish a baseline accuracy for existing atomization and vaporization models used in the prediction of a superheated spray by undertaking a critical review of existing experimental data available in the literature for validation. This work is funded through the supersonics (SUP) and subsonic fixed wing (SFW) project office initiatives on high altitude emissions of the NASA’s fundamental aeronautics program.

In what follows we first provide some details of the two superheat vaporization models that we have implemented into NCC. It is followed by other model considerations that need to be taken into account as described in Sections 8.3 & 8.4.

8.1 Superheat Vaporization Model of Zuo, Gomes, & Rutland [62], and Schmel & Steeple [63-64]

It is based on an extension of the classical \( D^2 \)-theory. In the classical evaporation model, the thermal energy needed for evaporation is mostly furnished by the external heat transfer from the surrounding gas. Under superheat conditions, the characteristic vaporization time resulting from the external heat transfer from the surrounding gas is of the same order of magnitude as that resulting from the flash evaporation. The energy needed for vaporization at the droplet surface is partly provided by the superheat energy stored within the droplet and it is controlled by the droplet internal heat transfer. The modeling approach differs from the classical droplet vaporization models in three important ways: (1) under superheat conditions, the droplet surface mass fraction,
where the flash boiled vaporization rate, $\dot{m}_{k,\text{flash}}$, is given by

$$
\dot{m}_{k,\text{flash}} = 4\pi r_k^2 \alpha_s \left( T_k - T_b \right) \frac{k}{l_k}
$$

where $T_k$ is the internal droplet temperature and the overall heat transfer coefficient, $\alpha_s$ (in W/m²°C) is given by the Adachi correlation [65]:

$$
\alpha_s = \begin{cases} 
0.76(T_k - T_b)^{0.26} & (0 \leq T_k - T_b \leq 5) \\
0.027(T_k - T_b)^{2.33} & (5 \leq T_k - T_b \leq 25) \\
13.8(T_k - T_b)^{0.29} & (T_k - T_b \geq 25)
\end{cases}
$$

The Adachi correlation is valid over a wide range of superheat conditions.

The vaporization rate due to external heat transfer, $\dot{m}_{k,t}$, in Eq. (56) is given by

$$
\dot{m}_{k,t} = 2\pi r_k k \frac{N u}{C_p} \left[ 1 + \frac{m_{k,\text{flash}}}{m_{k,t}} \right] \frac{\ln\left( 1 + \frac{m_{k,\text{flash}}}{m_{k,t}} \right)}{B_t}
$$

where the Spalding heat transfer number, $B_t$, and the Nusselt number, $N u$, are given by

$$
B_t = \frac{C_p(T_g - T_{k,s})}{l_{k,\text{eff}}}
$$

$$
N u = 2(1 + 0.3 Re^{1/2} Pr_l^{1/3})
$$

The corresponding droplet regression rate, $\frac{ds_k}{dt}$, is given by

$$
\frac{ds_k}{dt} = -\frac{\dot{m}_k}{2\pi r_k \rho_l}
$$

This model is valid over an entire range of superheat conditions as long as there is some amount of superheat energy available within the droplet ($T_k > T_b$).

8.2 Superheat Vaporization model of Lee et al. [74]

This modeling approach is also based on an extension of the classical $D^2$-theory but it differs from the previous model of [62, 63-64] in several important ways: (1) neglects the effects of internal nucleation and convection, (2) instead of invoking the Adachi correlation for the flush induced vaporization rate, the heat loss from the droplet interior is modeled by

$$
\dot{q}_i = \frac{T_{\text{interior}} - T_s(P_{\infty})}{r_{k,t=0}}
$$

(3) the formulation is valid only when $T_{\infty} \geq T_{bub}(P_{\infty})$, which means for positive Spalding heat transfer numbers.

With the assumptions employed, Lee et al. [74] arrived at the following equation for the evaporation rate, $\dot{m}_v$.

$$
\dot{m}_v \left( \frac{T_{\infty} - T_s}{c_{m_v} - 1} \right) = \dot{m}_v \hat{L} - \dot{q}_i
$$

where

$$
\hat{L} = \frac{C_p \rho_g T_s}{L_e}
$$

and $\dot{q}_i$ is the total evaporation rate, $\dot{m}_v$ is given by the computer coding provided by UTRC.

It is noteworthy that because of the assumptions invoked in this model, the applicability of this model may be limited in several important ways: (1) our experience shows that the assumption of $T_{\infty} \geq T_{bub}(P_{\infty})$ becomes too restrictive in most non-reactive calculations and also in some regions of most reactive spray calculations, and (2) the $\dot{q}_i$ term is modeled based on the assumption that the overall droplet life is very short (sub millisecond range) but in moderate superheat conditions the droplet lifetimes are on par with those vaporizing under non-superheat conditions. So its use is likely to be restricted for the modeling of smaller droplets produced after flash induced atomization.

The solution for Eq. (63) and all the JPS fluid properties needed in this calculation were obtained by the computer coding provided by UTRC.

8.3 Vaporization Model Valid Under Non-Superheat Conditions

Under moderate initial superheat conditions, only a fraction of the vaporization takes place under
superheat conditions \( T_k > T_b \) and the remainder takes place under non-superheat evaporating conditions \( T_k \leq T_b \). So there is a need to revert back to a vaporization model valid under stable evaporating conditions when the internal droplet temperature approaches the boiling temperature. In the present calculations, the vaporization rate under normal evaporating conditions is evaluated by means of a simplified classical \( D^2 \)-theory:

\[
\dot{m}_k = 2\pi r_k \rho_g D_{fgs} \text{Sh} \ln(1 + B_k) \tag{64}
\]

where the Spalding mass transfer number, \( B_k \), is given by Eq. (24) and the Sherwood number, \( \text{Sh} \), is given by

\[
\text{Sh} = 2\left(1 + 0.3 Re^{1/3} Sc_g^{1/3}\right) \tag{65}
\]

8.4 Internal Droplet Temperature Calculation

Our experience with the validation studies showed us that there is a definite need to include a calculation involving the internal droplet temperature valid under both superheat and normal evaporating conditions. In our present calculations, it was evaluated by means of a simple infinite conductivity model.

\[
\frac{dT_k}{dt} = \frac{3[l_{k,\text{eff}} - l_k] ds_k}{2C_p r_k^2} \tag{66}
\]

if \( T_k < T_b \), and

\[
\frac{dT_k}{dt} = -\frac{3\alpha_s}{r_k \rho_l C_{pl}}(T_k - T_b) \tag{for the superheat model of [62, 63 – 64])
\]

or

\[
\frac{dT_k}{dt} = -\frac{3\lambda_t}{r_k \rho_l C_{pl}} \frac{\partial T}{\partial r} \Big|_{ls} \tag{67}
\]

\( (for \ the \ superheat \ model \ of \ [74]) \)

if \( T_k \geq T_b \)

9 SUPERCritical droplet

VAPORIZATION

There is a need for understanding droplet vaporization behavior at supercritical conditions because of the increasingly high operating pressures encountered in some gas-turbine combustors. The engine operating pressures can exceed the supercritical pressure of liquid fuels such as jet-a. Because of its practical and fundamental importance, several experimental and theoretical investigations were undertaken to understand droplet gasification occurring at supercritical conditions [19-20, 82-86]. Most of the numerical investigations that appeared in the literature to study the vaporization behavior of an isolated single spherical droplet were based on the coupled twophase, unsteady Navier-Stokes equations in 1-D spherical coordinates [20, 83-86]. However, it is noteworthy that the resulting gas-liquid interface analysis at the droplet surface becomes extremely complicated for a multi-component mixture. Also, the numerical solution is complicated by several factors as it needs to take into account the high-pressure corrections associated with various transport and thermo-physical properties. The supercritical droplet vaporization differs from low-pressure droplet vaporization models in several important ways. For example, the results of Zuo et al [85-86] showed that under low to moderate temperatures, first there would be an increase in droplet lifetime before it starts to fall off with an increase in pressure. Their results also showed that there would be a monotonic decrease in droplet lifetime with increase in pressure at high ambient temperatures.

However, none of these analyses could be directly incorporated into a comprehensive spray calculation because of any such detailed treatment would be prohibitively expensive in terms of the required computer CPU resources. Also, they fail to address how to handle the supercritical droplet vaporization in a real gas-turbine environment in which a droplet traverses through a non-stagnant gas. Since our main interest lies in implementing a viable high-pressure droplet vaporization model into our spray code, we attempted to incorporate some important aspects of high pressure modeling derived from Refs. [20, 83-86] into the existing framework of our spray formulation. In what follows we describe some important aspects of supercritical droplet vaporization:

1. The non-idealities in gas-phase become increasingly more pronounced as the pressure approaches a supercritical state. There are several widely used equations of state that provide accurate representation at high pressures, namely the Peng
Robinson (PR), Redlich-kwong (RK), and Soave-Redlich-Kwong (SRK). In our calculations, we implemented the PR EOS because of its simplicity and also known to provide accurate representation [85-86]. Also, it is known to provide reasonable results when calculating the phase equilibrium at the droplet surface.

(2) At low pressure conditions, the solubility of the ambient gases in liquid phase can be neglected. The corresponding gas-phase composition at the droplet interface can be calculated by means of Raoult’s law, Eq. (42). At high pressures, the phase equilibrium calculations at the droplet surface need to take into account fugacity of each individual species. More on how to evaluate the phase equilibrium at the droplet surface can be found in Section 9.1.

(3) Both liquid and gas compositions encountered in a gas turbine combustion device are truly multi-component in nature. However, all the numerical investigations reported so far on supercritical droplet vaporization are based on a binary mixture [19-20,83-86]. Even for a binary mixture, the phase equilibrium calculations at high pressures present a formidable challenge. As it becomes very difficult to solve anything other than a binary mixture, we restrict the phase equilibrium calculations to a binary mixture involving a combination of a single-component surrogate fuel and nitrogen. Such a combination seemed to provide a reasonable representation for a fuel droplet vaporizing at high pressures [85-86].

(4) The transport properties in both liquid and gas phases become increasingly pressure dependent at high pressures. More on how we evaluate the transport properties at high pressures can be found in Sections [4] & [7].

(5) As the droplet surface approaches a transcritical state, the latent heat of vaporization diminishes to zero. In our current calculations, the latent heat of vaporization is calculated by a formulation as described in Section 9.2.

(6) The solubility of the ambient gases in liquid phase becomes increasingly important at high pressures. However in our present calculation, we ignore to take into consideration the multi-component nature of droplet behavior for the following reasons: For gas turbine combustors of our interest, the gas pressure seldom exceeds more than twice the critical pressure of jet fuels. Within that pressure range, the liquid phase solubility of gas could be ignored since it could be shown from phase equilibrium calculations that the liquid-phase mass fraction of nitrogen remains less than three percent even when the droplet surface temperature reaches near critical temperature.

(7) Zhu et al. [85-86] studied the influence of gas-phase unsteadiness on droplet vaporization, and also quantified to some degree the resulting differences from the quasi-steady and transient models. Their results show that unsteadiness seemed to persist over a wide region during a brief early transient period after a droplet is suddenly introduced into an otherwise stagnant gas. After this initial transition period, some unsteadiness remains persistent in a small region closer to the droplet surface. Initially, the quasi-steady model seemed to produce a smaller regression rate when compared with the transient model. But in the later stages of droplet lifetime, it seemed to produce a much higher regression rate. The influence of unsteadiness seemed to increase with an increase in both ambient pressure and temperature. However in our present calculations, we expect for the quasi-steady model to provide a useful approximation for the following reasons: (1) We are interested mainly in gas pressures not too far above the critical pressure of the liquid fuel, and (2) Also, we are interested in a droplet moving a stratified gas where the unsteadiness associated with initial transient can be neglected. It is because our droplet models are based on what happens after the initial atomization phase. So the neglected influence of unsteadiness is mostly limited to a small region near the droplet surface.

9.1 Equilibrium Relations Valid at High Pressure Conditions

At high pressures, the equilibrium needs to satisfy

\[ T^L = T^V \]

\[ P^L = P^V \]

\[ f_i^L = f_i^V \Rightarrow \ x_i \phi_i^L = y_i \phi_i^V \]

where \( f_i \) is the fugacity of the \( i \)th species, \( x_i \) is the mole fraction species in the liquid phase, \( y_i \) is the mole fraction species in the vapor phase, and \( \phi_i \) is the corresponding fugacity coefficient of the \( i \)th species which is given by
\( \ln \phi_i = \frac{b_i}{a_{i_m}} (Z - 1) - \ln (Z - B^*) + \frac{A^*}{2 \sqrt{2} B^*} \left( \frac{b_i}{a_{i_m}} - \delta_i \right) \ln \left( \frac{Z + B^*(1 + \sqrt{2})}{Z + B^*(1 - \sqrt{2})} \right) \)  

(71)

where \( \frac{b_i}{a_{i_m}} = \frac{T_{ea}/P_{ea}}{\sum y_i T_{ea}/P_{ea}} \), and

\( \delta_i = \frac{2a_{i}^{1/2}}{a_{i_m}} \sum x_j a_{j}^{1/2} (1 - k_{ij}) \). There are two more additional equations that need to be satisfied at the droplet interface,

\[ \sum_i y_i = 1 \]  

(72)

\[ \sum_i x_i = 1 \]  

(73)

For a given \( P \) and \( T \) of a binary mixture, there are six equations and six unknowns: \( Z_v, Z_l, y_1, y_2, x_1, \) and \( x_2 \). The Peng-Robinson EOS yields solution for \( Z_v \) and \( Z_l \) and the other four unknowns are calculated from the solution of Eqs. (70) to (73). The solution for this highly non-linear set of equations is obtained from the use of a Newton-Raphson iterative method.

### 9.2 Calculation of Latent Heat of Vaporization at High Pressure

The enthalpy of the species can be calculated from

\[ h_i = h_{i}^{v} - RT^2 \left[ \frac{\partial \ln \phi_i}{\partial T} \right]_{p, x_i} \]  

(74)

The related derivatives in the above equation are given by

\[ \frac{\partial h}{\partial a} = \frac{b_i}{6} \frac{\partial Z}{\partial T} - \left( \frac{\partial a}{\partial T} \right) + \frac{A^*}{2 \sqrt{2} B^*} \ln \left( \frac{Z + B^*(1 + \sqrt{2})}{Z + B^*(1 - \sqrt{2})} \right) \]  

(75)

\[ \frac{\partial a}{\partial T} = -RT \left( \frac{0.45724 T}{P_{ea}} \right)^{1/2} \]  

(76)

\[ \frac{\partial a^{1/2}}{\partial T} = \frac{R}{2} \left( \frac{0.45724}{T} \right)^{1/2} \sum_j y_j (1 - k_{ij}) \]  

(77)

\[ \frac{\partial a}{\partial T} = A^{1/2} \frac{\partial \phi}{\partial T} - 2 \frac{a}{T} \]  

(78)

\[ \frac{\partial a^*}{\partial T} = A^{1/2} \frac{\partial \phi}{\partial T} - 2 \frac{a^*}{T} \]  

(79)

Finally, once the enthalpies in both phases are known, the latent heat of vaporization is simply calculated as follows

\[ L_i = h_i^v - h_i^l \]  

(83)

### 9.3 ncc_hp_eos_vle_table.dat: A Table Containing the Equilibrium Properties of a Binary Mixture

Instead of performing these calculations on the fly, it would be a lot more economical to create a table containing the equilibrium properties of a binary mixture. Especially in gas-turbine combustor calculations we need to tabulate these properties for one given pressure. Based on the calculations described in Sections 9.2 to 9.3, we developed the coding necessary to create a table, ncc_hp_eos_vle_table.dat, that contains values for the following variables: latent heat and mole fractions of both species, density, compressibility factor \( (Z) \), and specific volume in both liquid and gas phases. The table contains incremental values over a wide range of expected liquid droplet temperatures for any given pressure. The values for any required temperature is calculated by means of linear interpolation.

### 10 DETAILS OF ATOMIZATION MODELING

Atomization refers to a process of the liquid jet breakup into droplets. There are many processes associated with the liquid jet breakup. They can broadly be classified into two regimes: (1) the inner nozzle flow, and (2) liquid behavior after exiting from the nozzle. In the inner nozzle flow, several factors (such as injector type, geometry, and size) influence the conditions at the injector exit (such as
the velocity, the initial sheet or jet thickness, and the angle of droplet dispersion). One way to specify the initial spray conditions at the injector exit is to rely on the widely-used correlations. For a better description, a more accurate analysis is needed which takes into account the physics associated with inside bubble growth, cavity formation, and internal turbulence. Once a liquid exits outside of the nozzle, it becomes unstable under the influence of aerodynamic instabilities and finally breaks up into droplets. The widely known aerodynamic instabilities are of Rayleigh-Taylor and Kelvin-Helmholtz kind [41, 43-44]. The Rayleigh-Taylor instability is due to inertia of the denser fluid opposing the system acceleration in a direction perpendicular to the interface of the denser fluid and the Kelvin-Helmholtz instability is caused by the viscous forces due to the relative motion of the fluids [43-44]. When the maximum amplitude of the most unstable wave reaches a critical value, some liquid is stripped of the main liquid core in the form of primary droplets. These droplets may further breakup into smaller droplets due to a process known as the secondary droplet breakup mechanism.

Based on a linear instability analysis of a 2D viscous incompressible fluid moving through an inviscid incompressible gas, Reitz and Bracco [41] characterized the break-up regimes to be four-fold: (1) Rayleigh breakup, (2) first wind-induced breakup, (3) second wind-induced breakup, (4) atomization. In the first two regimes, drops of sizes greater than or equal to the nozzle diameter are produced at distances far from the nozzle exit. In the applications of our interest, the last two regimes are more important where droplets much smaller than the nozzle diameter are produced near the nozzle exit. The knowledge gained from the instability analysis of various kinds [41, 45-46] is combined with some experimental observations to form the basis for various models developed for both primary atomization & secondary droplet breakup. In this approach, the jet breakup is modeled first by making use of a drop representation approach in which discrete parcels of liquid are injected in the form of blobs with a characteristic size representative of the nozzle diameter instead of tracking an actual intact liquid core that forms at the nozzle exit. In the case of a planar or conical liquid sheet, the discrete parcels essentially represent liquid ligaments. Before the jet breakup the discrete parcels stay inside of the liquid core or sheet but after the jet breakup they move independently. The breakup criterion, atomization rate, drop size and velocity and the location of the newly formed droplets are primarily determined based on an instability analysis derived from the conservation equations of mass, momentum and energy. The analysis of the jet or sheet breakup into ligaments or droplets, the stripping of the liquid into fragments or droplets, and the formation of more droplets from further breakup of ligaments or fragments are all described under the classification of primary atomization.

Some of the large droplets that are formed immediately after the primary liquid jet breakup may further breakup into smaller droplets under the influence of aerodynamic instabilities. The large droplets first tend to flatten under the influence of aerodynamic pressure. Then large amplitude long wavelength waves caused by drop deceleration induce a Rayleigh-Taylor instability on the flattened drop causing it to breakup further into several relatively large-size product droplets. While at the same time short surface waves induce a Kelvin-Helmholtz instability on the windward side of the parent drop resulting in the generation of much smaller product droplets. The breakup of the larger droplets into smaller droplets is described under the classification of secondary droplet breakup.

Most of the coding required for both the primary atomization and secondary droplet breakup models was provided by CFDRC. These models are applicable under both non-superheat and superheat conditions. In the superheated regime, the thermophysical liquid properties are replaced by the two-phase properties of a superheated fluid [74]. The CFDRC atomization module contains the following four primary atomization models: (1) the sheet breakup primary atomization model, (2) the blob jet primary atomization model, (3) the air-blast atomization model & (4) the BLS (Boundary-Layer Stripping) primary atomization model, and it also contains the following three secondary droplet breakup models: (1) the Rayleigh-Taylor secondary droplet breakup model, (2) the TAB (Taylor Analogy Breakup) secondary droplet breakup model, and (3) the ETAB (Enhanced TAB) secondary droplet breakup model. The choice between various models depends on the specific application. Complete details of the models contained in the atomization module can be found in the appendix.

10.1 Flash Atomization Modeling

There are three components to the atomization modeling of a superheat spray: (1) primary atomiza-
tion, (2) secondary droplet breakup, and (3) flash induced atomization. Further details of both primary atomization and secondary droplet breakup models are described in a previous section. For the superheated sprays, we have to deal with a third component known as flash induced atomization. We have followed the modeling approach of Lee et al. [74] for the flash induced atomization. In what follows we describe some details of their modeling approach.

Flash atomization is a result of rapid evaporation associated with strong nucleation and bubble growth occurring inside of a non-equilibrium two-phase fluid [74]. When the void fraction within the rapidly evaporating fluid reaches a certain critical void fraction, the inner liquid core would shatter into pieces. It seemed to have a value of 0.61 based on the research identified in [74]. Incidentally, this condition for criticality also coincides with the packing fraction associated with strong nucleation and bubble growth occurring inside of a non-equilibrium two-phase fluid [74]. When the void fraction within the droplets is defined as follows:

$$\frac{dx}{dt} = \frac{x_{eq} - x}{\theta} = \theta_{o} e^{\alpha \phi^3};$$  \hspace{1cm} (84)

where the values for $\alpha = -0.54$, $\beta = -1.76$, and $\theta_{o} = 6.51.10^{04}$ are taken from [76], and the void fraction, $\epsilon$, and the degree of superheat, $\phi$, are defined as follows:

$$\epsilon = \frac{\rho_1 - \rho_2}{\rho_1 - \rho_0}; \quad \phi = \frac{P_b(h) - P}{P_c - P_b(h)}$$  \hspace{1cm} (85)

Once the critical limit for the void fraction is reached, the resulting droplets produced as a result of flash atomization are obtained by a droplet number density correlation developed by Kawano et al. [77].

$$n = A e^{-\frac{E}{R_{gas} T}} e^{\alpha t + b}$$  \hspace{1cm} (86)

From Eq. (86), the mean droplet size, $\bar{R}$, is calculated by equating total liquid mass before and after the droplets are formed.

$$\bar{R}^3 = \frac{1 - \epsilon_c}{(4/3) \pi n}$$  \hspace{1cm} (87)

The solution for Eqs. (84) to (87) and all the JP8 fluid properties needed in this calculation were obtained by the computer coding provided by UTRC. Also, it is noteworthy that the properties for JP8 were predicted by means of a surrogate model of Violi. Further details can be found in [74].

The flash induced atomization is combined with the primary and secondary droplet breakup models following the approach of Lee et al. [74]. The aerodynamic instability mode will atomize the liquid core when the surface disturbance reaches a certain critical value and the flash induced atomization is responsible for shattering the liquid core when the void fraction reaches the critical value. Therefore, the control mechanism depends on whichever mechanism is first responsible for reaching the critical condition.

### 10.2 Some Effects of Superheat on Primary Atomization

Flash evaporation is known to produce a fine spray with enhanced atomization, increase effective spray cone angle, and decrease spray penetration [61]. Here, we consider the effects of flash evaporation on the sheet breakup primary atomization model by following the approach of Zuo et al [62]. Its effect on the initial droplet size generated immediately after the first ligament breakup, $d_{ls}$, is given as a function of both engine pressure and a superheat parameter.

$$d_{ls} = d_{in}\left(\frac{P}{P_{atm}}\right)^{0.27}[1 - \chi\left(\frac{P_{atm}}{P}\right)^{0.135}] \quad 0 \leq \chi\left(\frac{P_{atm}}{P}\right)^{0.135} \leq 1$$  \hspace{1cm} (88)

where $d_{in}$ is the corresponding droplet size occurring under normal evaporating conditions without flash evaporation, and $\chi$, a superheat parameter, is defined as follows:

$$\chi = \frac{I(T_{lv}) - I(T_{lv})}{I(T_{lv})}$$  \hspace{1cm} (89)

where $I$ is the internal energy of the liquid. Its value varies between $0 < \chi < 1$ with $\chi = 0$ referring to zero flash evaporation and $\chi = 1$ to full flash evaporation.

In Eq. (88), the increase in $d_{ls}$ due to an increase in engine pressure by a factor of $(P/P_{atm})^{0.27}$ is based on an experimental correlation obtained from Lefebvre [66]. It reflects the influence of chamber pressure on wave propagation as it damps wave growth. But the decrease by a factor of $(1 - \chi(P_{atm}/P)^{0.135})$ is due to a significant reduction in droplet size caused by both cavitation and bubble growth under flash evaporation conditions. It was introduced based on the experimental data obtained from VanDerWege et al [67] and Reitz [68].

As the liquid approaches boiling, it also causes a substantial decrease in both intact liquid core length...
and core droplet size leading to a modification of the nominal cone angle, $\theta$, as given by

$$\theta = \theta_n + (144 - \theta_n)\chi^2$$  \hspace{1cm} (90)

where $\theta_n$ is in degrees for a spray vaporizing under normal conditions without flash evaporation. This correlation was developed based on the experimental data of Reitz [68].

These two correlations were developed in conjunction with the sheet breakup primary atomization model but their application with other primary atomization models need further investigation.

11 DESCRIPTION OF INITIAL SPRAY CONDITIONS

The spray computations facilitate the use of multiple fuel injectors. The same or a different type of liquid fuel can be specified for each one of different injectors. The initial droplet temperature is assumed to be the same for all different droplet groups of a given injector. The liquid fuel injection is simulated by introducing a number of discretized parcels of liquid mass at the beginning of every fuel-injection time step, $\Delta t_{d\ell}$. The following three variables play an important role in simulating the injector initial conditions:

- $\text{no\_of\_holes}(\cdot)$ - the number of holes per injector,
- $\text{no\_of\_streams}(\cdot)$ - the number of droplet streams per hole - it is introduced to distinguish the initial velocity variation within different droplet classes arising from the geometric considerations of a chosen spray, &
- $\text{no\_of\_droplet\_groups}(\cdot)$ - the number of droplet groups per stream - it is introduced to distinguish the droplet-size variation within different droplet classes of a polydisperse spray.

The total number of droplet groups introduced at the beginning of every different injection time step for a given injector is therefore equal to a value given by the multiplication of these three variables. Further details on some of the spray input variables can be found in the spray input file, nccInjector.in.1 of Table 6, where the integer number followed by the last dot represents the injector number, which in this case happens to be one. The table provides a complete description of the following input variables: $\text{nolc}(n_i)$, $\text{out\_string}$, $(\text{ymki}(n_i,n_j,l=1), n_l=1, \text{nolc}(n_i))$, $\text{tdrop}(n_j)$, atomization$(n_i)$, drop_breakup_model$(n_i)$, spray_table$(n_i)$, steady_spray_model, $\text{no\_of\_holes}(n_i)$, $\text{no\_of\_streams}(n_i)$, $\text{no\_of\_droplet\_groups}(n_i)$, $\text{lnmdis}(n_i)$, $\text{smdm}(n_i)$, $\text{cone}(n_i)$, $\text{size\_min}(n_i)$, $\text{size\_max}(n_i)$, stochastic$(n_i)$, $((x_{inj}(n_i,nx), y_{inj}(n_i,nx), z_{inj}(n_i,nx), z_{inj}(n_i,nx), \text{flowf}(n_i,nx), v_{inj}(n_i,nx), v_{inj}(n_i,nx), \text{alpha}_{inj}(n_i,nx), \text{beta}_{inj}(n_i,nx), \text{theta}_{inj}(n_i,nx), \text{dtheta}_{inj}(n_i,nx), \text{swlr\_angle}(n_i,nx), n_{x=1,\text{no\_of\_holes}(n_i)})$, (atom_type$(n_i,nx)$), breakup_type$(n_i,nx)$, dia_hole$(n_i,nx)$, delp_inj$(n_i,nx)$, liq_vel$(n_i,nx)$, gas_u$(n_i,nx)$, gas_v$(n_i,nx)$, gas_w$(n_i,nx)$, pcl_start$(n_i,nx)$, pcl_end$(n_i,nx)$), $n_{x=1,\text{no\_of\_holes}(n_i)}$).

The initial droplet distribution for a given injector could be specified by making use of one of the three available options: (1) by providing a complete specification of the initial conditions through a spray table, (2) by invoking certain pre-defined correlations, or (3) by choosing one of four available primary atomization models. When Option (3) is selected, the logical variable, atomization$(\cdot)$, is set to .true. or otherwise it is set to .false..

Option (1):

When a spray table is defined, one should provide the information on the $(x, y, z)$ components of the initial droplet location, the $(u, v, w)$ components of the droplet velocity, and the initial mass flow rate associated with each different droplet group as described in ncc_spray_table.1 of Table 7. This table provides a complete description of the following variables: nos$(n_i)$, $(n_{i,xx_{inj}}, y_{inj}, z_{inj}, u_{inj}, v_{inj}, w_{inj}, a_{inj}, f_{d\ell})$, $n_{i=1,\text{nos}(n_j)}$). The initial inputs specified through a spray table should be representative of the integrated averages of the experimental conditions [10-13].

Option (2):

In this option, we need to specify several parameters including $\text{no\_of\_holes}(\cdot)$, $\text{no\_of\_streams}(\cdot)$, & $\text{no\_of\_droplet\_groups}(\cdot)$. And depending on what is specified for the input of the integer variable, lnmdis, in nccinjector.in.1, the droplet-size distribution within each one of the streams is determined based on the following three choices:

- In one choice, it is calculated based on a correlation typical of those widely used in describing the initial droplet size distribution [4]:

For 2D:
\[ \text{no_of_streams()}/2 \] is between \( OI \) to \( OO \), and
\[ \text{no_of_streams()}/2 \] is between \( LO \) to \( LI \).

Fig 4b. Initial spray particle concentration in a 2D planar case.
Figure 5 Droplet-size distribution.

\[ \frac{dn}{n} = 4.21 \times 10^6 \left( \frac{d}{d_{32}} \right)^{3.5} e^{-16.98\left( \frac{d}{d_{32}} \right)^{0.4}} \frac{dd}{d_{32}} \]  (91)

where \( n \) is the total number of droplets and \( dn \) is the number of droplets in the size range between \( d \) and \( d + dd \). This correlation also requires the specification of Sauter mean diameter, \( d_{32} \). Fig. 5 shows the droplet size distribution generated by Eq. (91) for a case studied in [10]. The solid line shows the droplet number variation versus drop size and the dashed line shows the integrated mass variation with drop size. The drop size distribution within the spray is represented by a finite number of droplet classes as given by the variable, no_of_droplet_groups().

- In the second choice, the initial droplet sizes are distributed evenly between two specified maximum and minimum drop sizes - size_max() & size_min() as specified in Table 6. And the size interval depends on the value specified for the variable, no_of_droplet_groups(). However, this option is applicable only in certain special cases.

- In the third choice, the initial droplet size distribution is calculated by making use of a clipped probability distribution function as given by

\[ P(\chi) = \int_0^\chi f(x)dx / \int_0^{12} f(x)dx \]  (92)

where \( f(x) = (1.0 - \exp(-x)(1+x+\frac{1}{2}x^2+\frac{1}{6}x^3)) \). After a random sampling of \( 0 < \chi < 12.0 \), the initial droplet diameter is determined as follows: \( 0.3 < 4P(\chi) < 1.5 \). If the value for \( 4P(\chi) \) goes beyond the limits of 0.3 and 1.5, the random sampling is reiterated until that number falls within the range of the lower and upper bounds.

Depending on what is specified for the logical variable, cone, of Table 6, the droplet velocity distribution amongst various streams of a given hole is calculated by assuming the spray to be either a solid or hollow cone spray. A graphical illustration of three different cone configurations are shown in Figs. 2 to 4. Figs. 2a & 2b refer to a 3D case, Figs. 3a & 3b to an axisymmetric case, and Figs. 4a & 4b to a 2D planar case. It is noteworthy that in an axisymmetric case, the x-axis is assumed to be aligned with the axis-of-symmetry.

Fig. 2a shows the geometric details of a hollow cone spray in 3D where \( \theta \) is known as the cone angle, \( d\theta \) is the half-cone angle, and for a solid cone spray \( d\theta = \theta/2 \). And \( \alpha \) represents the angular rotation from the x-y plane and \( \beta \) is the angular rotation from the x-axis. Fig. 2b shows initial spray stream orientation in a circular cross section. We try to simulate the spray by a finite number of streams as given by the variable, no_of_streams(). Each one of the dark circles in Fig. 2b represents a different stream. The streams are distributed evenly along each one of the different rays which are separated from each other with an angle of separation as given by \( \phi \). Currently, we have hard-coded the angle of separation to be 450 which means we have restricted the number of rays to be eight in 3D. Therefore, when specifying a number for no_of_streams(), it should be borne in mind that it should be a multiple of eight. And the number of streams along each one of the rays, therefore, becomes equal to no_of_streams()/8. In Fig. 2b, the no_of_streams() has a value of 32 and, therefore, the number of streams along each one of the rays for this case is 4.

Fig. 3a. shows the geometric details for an axisymmetric case. Since the computations are performed only in the first quadrant of the x-y plane, all of the specified number of streams, no_of_streams(), are distributed evenly between the lower and upper halves as shown in Fig. 3a and 3b. Here, the upper half refers to the region between OI to OO and the lower half refers to LO to LI. It is noteworthy that each
droplet group in a given stream represents a circular ring of liquid for an axisymmetric case.

The geometric details for a 2D case are shown in Figs. 4a & 4b. Here, it is noteworthy that each droplet group in a given stream represents a planar sheet of liquid. All the specified number of streams, no_of_streams(), are distributed evenly over both sides of the cone center as shown in Fig. 4b.

For each one of the different injector holes, no_of_holes(), it requires the specification of the following parameters as described in ncc_injector.in.1 of Table 6 (However, because of the geometric differences that exist between 3D, 2D, and axisymmetric configurations, some of the input parameters may have different units as noted below):

- The initial (x, y, z) coordinates of the hole location.
- The mass flow rate per hole - however, the definition of the units for the injector mass flow rate per hole differs: it is kgm/s for 3D & the axis-of-symmetry and kgm/s/m for 2D planar (note: In an axis-of-symmetry, the specified mass flow rate per hole refers to the entire mass flow rate over 360 degrees).
- The following variables define the angular orientation: \(\alpha_{inj}\) = angle of rotation from the x-y plane, \(\beta_{inj}\) = angle of rotation from the x-axis, \(\theta_{inj}\) = cone angle, & \(d\theta_{inj}\) = half-cone angle (note: Although \(d\theta_{inj} = \theta_{inj}/2\) for a solid cone spray, a specified value of zero for \(d\theta_{inj}\) also invokes a solid-cone spray configuration).
- The variable, swlr_angle(), allows a means to specify the tangential component in the case of both 3D and axisymmetric sprays.

**Stochastic Option**

In the above description of Option (2), the initial droplet conditions are determined based on a deterministic approach. However, such an approach when employed in 3D may lead to time consuming calculations requiring the use of many droplet groups. With this in mind, we wanted to introduce some randomness into the calculation of the initial droplet velocity distribution as an option. This option can be invoked by setting the logical variable, stochastic(), to be .true.. In a stochastic approach, the initial angular orientation of a particle could be randomized in a number of different ways. The obvious way would be to determine the initial droplet direction based on a complete randomization in a field as defined by the geometric parameters: solid cone angle, \(\theta\), half cone angle, \(d\theta\) and/or azimuthal angle, \(\phi\). Another way is to try to retain the basic features of the deterministic approach where the initial droplet directions are taken as the means in a random field with the randomness localized to within the surrounding angular sub-segment of the respective droplet as represented by \(d\theta, \delta d\theta, \delta d\phi, \text{or } \delta d\theta \delta \phi\). We have chosen to go with the later option as it preserves the same basic structure but provides some benefits of the stochastic approach.

**Option (3):**

Here many aspects of fuel injection remain the same as in Option (2) but the initial droplet size and velocity distribution may differ depending upon the primary atomization model selected. More details on the available primary atomization models can be found in the appendix. For each one of the different injector holes, no_of_holes() it requires the specification of all the parameters as in Option (2). However, it doesn't make use of the values set for size_max() & size_min(). Also, it requires the specification of some additional parameters as described in ncc_injector.in.1 of Table 6. However, there exist some differences with regard to their usage depending upon the primary atomization model. Some major differences are highlighted below:

- The integer variable, atom_type() of Table 6, is used to select the primary atomization model of one's choice.
- dia_hole() needs to be specified for all primary atomization models.
- delp_inj() needs to be specified only with the sheet breakup primary atomization model and it is used in Eq. (9) of the appendix.
- liq_vel(n_i,nx), gas_u(n_i,nx), gas_v(n_i,nx), gas_w(n_i,nx), pcl_start(n_i,nx), & pcl_end(n_i,nx)) are required only for the air-blast primary atomization model.

In all of the primary atomization models except for the air-blast, the total number of droplet groups (particles) to be injected at the time of every injection period is specified through the use of the variable, no_of_droplet_groups().
Fig. 6 A graphic illustration of a multi-point (line) injection.

Fig. 7 A graphic illustration of a multi-point (circular) injection.
For the air-blast, it is given by \( pcl_{\text{end}}(n_i,nx)-pcl_{\text{start}}(n_i,nx)+1 \).

- In this option, all of the injected droplet groups as specified by either \( \text{no_of_droplet_groups}() \) or \( pcl_{\text{end}}(n_i,nx)-pcl_{\text{start}}(n_i,nx)+1 \) are distributed randomly across the entire cross-section of any selected 2D, axisymmetric, or 3D spray configuration. So it is recommended that \( \text{no_of_streams}() \) be set equal to one as no distinction is made between streams.

The secondary droplet breakup option can be invoked regardless of how the initial droplet conditions are generated using Options (1) to (3). The secondary droplet breakup option can be invoked by setting the logical variable, \( \text{drop_breakup_model}() \), to be .true.. And then the integer variable, \( \text{breakup_type}() \) of Table 6, is used to select the secondary droplet breakup model of one’s choice. More details on the available secondary droplet breakup models can be found in the appendix.

12 MULTI-POINT (LINE OR CIRCULAR) SPRAY INJECTION

In order to perform some reacting spray calculations involving a GE Taps concept which was developed as a part of the NASA’s fundamental aeronautics/supersonic initiative on high altitude emissions, we implemented some new methods of spray injection into our spray code: (1) a line injection, and (2) an injection along a circular arc.

In line injection, a new droplet is injected randomly between two end points of a line as specified by \((x_i, inj, y_i, inj, z_i, inj)\) and \((x_{f, inj}, y_{f, inj}, z_{f, inj})\). The initial droplet velocity is defined by a velocity magnitude as specified by \( V_{\text{inj}} \) and its orientation as specified by an angle, \( \beta_{\text{inj}} \), in degrees. Within the line injection, we have added two different options: (1) line injection with a full cone angle, and (2) line injection with a half cone angle. In both these options the angle is given by \( \theta_{\text{inj}} \) in degrees, and a newly injected droplet is chosen randomly to fall within the specified cone angle. A graphic illustration of the line injection with a full cone angle is shown in Fig. 6.

In circular injection, a new droplet is injected randomly along a circular arc between two end points along the circumference of a circle. For this case, the coordinates of the circular arc are specified by the following parameters: its center location, \((x_{i, inj}, y_{i, inj}, z_{i, inj})\), its radius, \( r_{i, inj} \), and the angular location of its two end points, \( x_{f, inj} \) and \( y_{f, inj} \) in degrees. The initial droplet velocity is defined by a velocity magnitude as specified by \( V_{\text{inj}} \) and its orientation as specified by an angle, \( \beta_{\text{inj}} \), in degrees. Within the circular injection, we have added two different options: (1) circular injection with a full cone angle, and (2) circular injection with a half cone angle. In both these options the angle is given by \( \theta_{\text{inj}} \) in degrees, and a newly injected droplet is chosen randomly to fall within the specified cone angle. A graphic illustration of the circular injection with a full cone angle is shown in Fig. 7.

It is also important to note that the initial droplet size is determined based on a given value for SMD and a clipped probability density function as given by Eq. (92). And the number of droplets in a given parcel, \( n_k \), is determined based on the initial liquid mass flow rate and the specified value for \( \text{no_of_droplet_groups}(n_i) \).

13 SPRAY SOLUTION ALGORITHM

In order to evaluate the initial conditions that are needed in the integration of the liquid-phase equations, we first need to know the surrounding gas-phase properties at each particle location. But in order to evaluate the gas-phase properties, it is first necessary to identify the computational cell in which a given particle is located. It is a trivial task to track a particle in the regular rectangular coordinates. However, the particle tracking becomes complicated when the computational cell is no longer rectangular in the physical domain and it becomes even more complicated when the particle search is performed within the context of parallel computing.

We have developed and implemented an efficient particle-tracking algorithm for use with parallel computing in an unstructured grid. The search is initiated in the form of a local search originating from...
the computational cell in which the same particle was found to be located in the previous time step. The location of the computational cell is then determined by first evaluating the dot product of \( \mathbf{x}_{\text{pc}} \cdot \mathbf{a}_n = |\mathbf{x}_{\text{pc}}| |\mathbf{a}_n| \cos(\phi) \), where \( \mathbf{x}_{\text{pc}} \) is the vector defined by the distance between the particle location and the center of the n-face of the computational cell, \( \mathbf{a}_n \) is the outward area normal of the n-face as shown in Fig. 8, and \( \phi \) is the angle between the two vectors.

A simple test for the particle location requires that the dot product be negative over each and every one of the n-faces of the computational cell. If the test fails, the particle search is carried over to the adjacent cells of those faces for which the dot product turns out to be positive. Some of those n-faces might represent the boundaries of the computational domain while the others represent the interfaces between two adjoining interior cells. The search is first carried over to the adjacent interior cells in the direction pointed out by the positive sign of the dot products. The boundary conditions are only implemented after making sure that all other remaining possibilities point towards a search exterior of the computational domain. This implementation ensures against any inadvertent application of the boundary conditions before the correct interior cell could be identified.

After the gas-phase properties at the particle location are known, the solution for the ordinary differential equations of particle position, size, and velocity are advanced by making use of a second-order accurate Runge-Kutta method. The partial differential equations governing the droplet internal thermal and mass transport are integrated by making use of a fully implicit Newton-Raphson iteration method.

Finally, the liquid-phase source terms of the gas-phase conservation equations (1-4) are evaluated by making use of a time-averaging method.

14 DESCRIPTION OF COMPUTER FLOWCHART, & THE TIME-AVERAGING SCHEME USED IN THE GAS-PHASE SOURCE-TERM CALCULATIONS

- In order to know more about the time-averaging method, we need to know first about the three different time steps that are internal to the spray code: \( \Delta t_{ml} \), \( \Delta t_{il} \), and \( \Delta t_{gl} \).

\( \Delta t_{ml} \) - the actual time step used in integrating the liquid-phase equations which is determined based on the smallest of the different time scales associated with various rate-controlling phenomena of a rapidly vaporizing droplet.

\( \Delta t_{il} \) - the injection time step. It is the time step at which a new discretized parcel of different droplet groups are introduced into the computation.

\( \Delta t_{gl} \) - the global time step. Its introduction seems to provide better convergence in both unsteady and steady-state computations.

- When the spray solver is called it advances the liquid phase equations over a number of iterations as determined by the ratio of \( \Delta t_{gl}/\Delta t_{ml} \).

- It then evaluates the time-averaged contribution of the liquid-phase source terms, \( S_{gl} \), of the gas-phase governing equations (1-4) as follows:

\[
S_{gl} = \sum_{m=1}^{M} \Delta t_{ml} \Delta t_{gl} S_{ml} \quad (93)
\]

where

\[
\sum_{m=1}^{M} \Delta t_{ml} = \Delta t_{gl} \quad (94)
\]

- The values for \( \Delta t_{ml}, \Delta t_{gl}, \) & \( \Delta t_{il} \) are specified in the input file, ncc_liquid_solver.in, of Table 8.

- In steady-state computations, it is recommended to use for both \( \Delta t_{gl} \) and \( \Delta t_{il} \) a value of about 1 ms which is roughly equivalent to the average lifetime of the droplets for a typical reacting spray encountered in conventional low-pressure gas-turbine combustors.

The averaging scheme could be explained better through the use of a flow chart shown in Fig. 9. The main spray solver is invoked with a controlling routine, DCLR, which, then, executes the following steps:

1. It first initializes the source terms to zero.
2. Updates the global time, \( t_{gl} \), based on \( \Delta t_{gl} \).
3. Checks to see if \( t_{ml} < t_{gl} < t_{ml} + \Delta t_{ml} \). If it is, it returns control over to the calling routine and supplies the other flow solvers, e.g., flow or EUPDF, with the source terms, \( S_{gl} \), of Eqs. (1)-(4). If not, it proceeds with the next step.

4. Checks to see if it is time to introduce a new group of particles.

5. Proceeds with solving the liquid-phase equations with calls to the following routines:
   - Calls the particle tracking routine and assigns particles based on the parallel strategy implemented.
   - Interpolates gas-phase properties at the particle location.
   - Advances liquid-phase equations and, then, deletes any particles that are no longer needed in the computations.

6. Evaluates the liquid-phase source-term contributions, \( S_{ml} \), of Eq. 93.

7. Updates the time, \( t_{ml} \), based on \( \Delta t_{ml} \).

8. It then goes back to step (3) and repeats the whole process again until the computations are completed over a global time step:
   \[ \sum_{m=1}^{M} \Delta t_{ml} = \Delta t_{gl}. \]

15 IMPLEMENTATION OF BOUNDARY CONDITIONS

The spray code supports all of the boundary conditions that exist in the current version of the NCC CFD module. First, we are going to provide a summary of the droplet and wall interaction models. There are several possible outcomes following a droplet impact with a wall. They can be broadly classified into four categories: (1) the droplet may move along a wall after its impact but still keeps on vaporizing, (2) the droplet may rebound after its impact with the wall, (3) the droplet may stick to the wall after its impact but keeps on vaporizing, or (4) the droplet may be shattered after its impact with the wall. The first outcome is the default boundary condition that was originally implemented into our code. It is based on the assumption that a droplet, after having lost most of its momentum upon impingement with the walls, moves along the wall surface with a velocity closer to that of the surrounding gas-film. The last three outcomes are based on the models described in Refs. [80-81]. They are implemented partially based on the coding received from CFDRC.

In order to implement the droplet and wall interaction models, there is a need to determine the intersection location of a particle crossing a wall, \( x_{bl,k} \). It can be determined based on the known initial particle location, \( x_{ik} \), particle velocity, \( V_{ik} \), and other geometrical considerations of the grid cell. Based on vector analysis, we have determined it as follows

\[ x_{bl,k} = (x_{ik} + u^* u_{ink}, y_{ik} + u^* v_{ink}, z_{ik} + u^* w_{ink}) \]  
(95)

where

\[ u^* = \frac{a_n (x_{cwf} - x_{ik})}{a_n V_{ink}}, \]

\( V_{ink} \) is the velocity normal \((= \frac{V_{ik}}{|V_{ik}|})\), and \( x_{cwf} \) is the center location of the wall face of the grid cell. In what follows, we define various variables - Reynolds number, \( Re_{sw,k} \), Weber number, \( We_{sw,k} \), Ohnesorge number, \( Oh_{sw,k} \), surface energy, \( E_{sw} \), and viscous dissipation, \( V_{dis} \) - used in the spray-wall interaction modeling.

\[ Re_{sw,k} = \frac{2 \rho_k r_k |V_{ik}|}{\mu_k} \]  
(96)

\[ We_{sw,k} = \frac{2 \rho_k r_k |V_{ik}|^2}{\sigma_k} \]  
(97)

\[ Oh_{sw,k} = \frac{\sqrt{We_{sw,k}}}{Re_{sw,k}} \]  
(98)

\[ E_{sw} = \pi \sigma_k (2r_k \beta_{max})^2 (1 - \cos \alpha)/4 \]  
(99)

where

\[ \beta_{max} = \frac{\sqrt{12 + We_{sw,k}}}{3(1 - \cos \alpha)} + \frac{4 We_{sw,k}}{\sqrt{Re_{sw,k}}}, \]

the droplet impact angle, \( \alpha \), is given by

\[ \alpha = \frac{\pi}{2} - \cos^{-1} \gamma, \]

and the droplet frequency, \( \gamma \), is

\[ \gamma = \frac{(x_{bl,k} - x_{ik}) a_n}{2r_k}, \]

and

\[ V_{dis} = \frac{2 \pi r_k \rho_k |V_{ik}|^2 (2r_k \beta_{max})^2}{3 \sqrt{Re_{sw,k}}} \]  
(100)

The droplet outcome after the interaction with the wall is determined based on the following criteria:
**Shattering Droplet:**

A droplet shatters upon impact with a wall when $W_{e,sw,k} > W_{e,crit}$, where the critical Weber number is defined as follows

$$W_{e,crit} = 9.9^{10} Oh^{2.8}$$  \hspace{1cm} (101)

The average size of the shattered droplet size after impact is given by

$$r_{ave,shat} = \max (r_{l1,shat}, r_{l2,shat})$$  \hspace{1cm} (102)

where $r_{l1,shat}$ and $r_{l2,shat}$ represent the two limits of droplet sizes as determined by

$$r_{l1,shat} = \frac{\sigma_k W_{e,crit}}{2 \rho_k |V_{ik}|^2}$$  \hspace{1cm} (103)

$$r_{l2,shat} = \frac{4\pi r_k^3 \sigma_k}{E_{sw}}$$  \hspace{1cm} (104)

Once $r_{ave,shat}$ is determined, the total number of shattered droplets produced is given by

$$N_{shat} = \text{int}[\left( \frac{r_k}{r_{ave,shat}} \right)^3]$$  \hspace{1cm} (105)

However, it is important to note that the number of shattered droplets generated is limited to 2 as shown below

$$N_{shat} = \min(2, \text{int}[\left( \frac{r_k}{r_{ave,shat}} \right)^3])$$  \hspace{1cm} (106)

The actual size of the shattered droplets is calculated by introducing some randomness as shown below

$$r_{shat} = r_{ave,shat}(0.85 + 0.30 \text{RND})$$  \hspace{1cm} (107)

where RND is a random number between (0,1). The droplet position and velocity of the shattered droplets is determined by the following criteria.

Upon impact with a wall, a shattered droplet emerges from the wall in a direction determined by the modified reflection normal vector, $\vec{x}_{rnk}$.

$$\vec{x}_{rnk} = 2(0.5 - \text{RND})(\vec{x}_{ink} - C_{res}(\vec{x}_{ink} - \vec{a}_n) \vec{a}_n)$$  \hspace{1cm} (108)

where $C_{res}$ stands for coefficient of restitution. Its value depends on the properties of the wall but has a value of 2 under normal reflecting conditions. Also, $\vec{x}_{ink}$ is added to introduce some randomness into the direction of reflection vector. Once $\vec{x}_{rnk}$ is determined, the new droplet position and velocity are calculated.

$$\vec{x}_{nk} = \vec{x}_{bl,k} + |\vec{x}_{bk} - \vec{x}_{nk}| \vec{x}_{rnk} + C_{off} \vec{a}_n$$  \hspace{1cm} (110)

where $C_{off}$ stands for offset and is usually assigned a tiny value but in our present calculations it is assigned a value of 0.01$|x_{cwf} - x_{cgc}|$, where $x_{cgc}$ is the center location of grid cell.

$$\vec{V}_{nk} = V^{0.6}_{nk} \vec{a}_n$$  \hspace{1cm} (111)

$$\vec{x}_{nk} = \vec{x}_{bl,k} + C_{off} \vec{a}_n$$  \hspace{1cm} (112)

Once the droplet size, location, and velocity of the shattered droplets are determined, the rest of the droplet properties can easily be deduced from the initial conditions of incident droplet.

**Sticking Droplet to the Wall:**

A droplet sticks to the wall when $E_{sw} < V_{dis}$. After being stuck to the wall, the impacted droplet size remains the same but continue to vaporize in time. The droplet velocity and position are assigned the following values:

$$\vec{V}_{nk} = 10^{-06} \vec{a}_n$$  \hspace{1cm} (113)

$$\vec{x}_{nk} = \vec{x}_{bl,k} + C_{off} \vec{a}_n$$  \hspace{1cm} (114)

The rest of the droplet properties are deduced from the initial conditions of incident droplet.

**Rebounding Droplet:**

If none of the above conditions are met for the outcomes of either droplet shattering or droplet sticking to a wall, the droplet is assumed to rebound after its impact with a wall. After the rebound, the droplet size remains intact as in the incident droplet. Both the droplet velocity and position are calculated as
in the droplet shattering but randomness is removed from the reflection vector. So it is calculated as in Eqs. (109-112) but RND is assigned a value of zero. The rest of the droplet properties are deduced from the initial conditions of incident droplet.

Moving Droplet Along the Wall:

For those droplets that were produced as a result of droplet shattering, they are assumed to move along next to the wall surface after its subsequent impact with a wall. Such a droplet would experience no change in its size after its impact but it is allowed to keep on vaporizing as it moves along the wall surface. The droplet velocity and position are calculated as follows

\[ V_{nk} = V_{gs} \]  \hspace{1cm} (115)

\[ x_{nk} = x_{bl,k} + C_{off} a_n \]  \hspace{1cm} (116)

where \( V_{gs} \) is the velocity of the surrounding gas.

Finally, in what follows we highlight how some other boundary conditions are implemented:

- The implementation of the periodic boundary conditions becomes rather complicated. It is because one needs to keep track of a particle leaving the computational domain from one periodic boundary, and for every particle that leaves the domain, a second particle reenters the computational domain through a corresponding second periodic boundary. Also, one needs to take into account the possibility of the two computational cells where the particles leave and reenter the domain being assigned to a different processor. We incorporated the periodic implementation as a part of the particle search algorithm. It is important to note that the boundary conditions are implemented with the help of some appropriately defined transformation matrices. Also, the particle velocities of the entering particle need to be adjusted accordingly based on the orientation of respective periodic boundaries.

- The symmetric boundary condition is implemented in such a way to satisfy the criterion that for every particle crossing the symmetry line, a similar one re-enters the domain in a direction determined by the reflection vector.

- When the particles move out of the exit boundary, they are taken out of the computation.

16 DETAILS OF COUPLING BETWEEN LSPRAY-V AND OTHER SOLVERS

- The spray code is designed to be a stand-alone module such that it could easily be coupled with any other unstructured-grid CFD solver and the same holds true for EUPDF. (However, some grid-related parameters such as area vectors, grid connectivity parameters, etc. need to be supplied separately).

- The spray solver needs information on the gas velocity and scalar fields from the other solvers and, then, it in turn supplies the liquid-phase source terms.

- The PDF solver needs information on the mean gas velocity, turbulent diffusivity and frequency from the CFD solver and the liquid-phase source terms from the spray solver, and then it in turn provides the solution for the scalar (species and energy) fields to the flow and spray solvers.

- It should also be noted that both the PDF and spray solvers are called once at every other specified number of CFD iterations.

- All of the three solvers (LSPRAY-V, EUPDF, and CFD) are advanced sequentially in an iterative manner until a converged solution is obtained.

- All three codes (EUPDF, CFD, and LSPRAY-V) were coupled and parallelized in such a way to achieve maximum efficiency.

The coupling issues could be better understood through the use of a flow chart shown in Fig. 10. It shows the overall flow structure of the combined CFD, LSPRAY-V, and EUPDF modules. Both the PDF and spray codes are loosely coupled with the CFD code. The spray code is designed in such a way that only a minimal amount of effort is needed for its coupling with the flow and PDF solvers. The present version of the spray module relies entirely on the use of Fortran common blocks for its information exchange with other modules. Even this reliance should entail only few changes to be made within the
Fig. 10 The overall flowchart of the combined CFD, LSpray, and EUPDF solvers.
spray code for its linkage with different solvers. The PDF code is also structured along similar coupling principles.

The flow chart of Fig. 10 contains several blocks - some shown in black and/or solid lines and the others in color and/or dashed lines. The ones in solid blocks represent the flow chart that is typical of a CFD solver. The ones in dashed blocks represent the additions arising from the coupling of the spray and PDF solvers.

The coupling starts with the calling of the subroutine - spray_pdf_read_parameters, which then reads the spray control parameters from the input file, ncc_liquid_solver.in of Table 8. This table provides a detailed description of the following input file variables - ldread, ispray_mod, (when_start_spray(n_l), n_l=1,no_of_injectors), iswim, wall_film_thickness, offset, coef_of_restitution, hp_eosl, dtml, dtgl, & dtl. The coupling is then followed by the calling of the pdf_int_rerun subroutine. It initializes PDF computations and also it may restart the PDF computations if needed from the data stored from a previous iteration. Similarly, we call spray_int_rerun for the spray computations.

It is noteworthy that the spray computations can be restarted by reading the data from the restart files: ncc_liquid_params.out, ncc_liquid_results.db, & ncc_liquid_results_mc.db. The restart capability is invoked by setting the logical variable, ldread, of the input file, ncc_liquid_solver.in of Table 8, to be true. Otherwise, the spray computations are initialized to start from the beginning. Then, the coupling proceeds with the calling of the following subroutines: dclr for integrating the spray calculations and eupd for the Monte Carlo PDF. The input variable, ispray_mod of Table 8, controls the calls to the spray integrating routine. The spray solver is called once at every other number of CFD iterations as specified by ispray_mod. And the first call to the spray solver is controlled by the input variable, when_start_spray(), of Table 8, which represents the starting CFD iteration number from which the spray computations are initiated. Finally, the coupling ends with the calling of a subroutine, spray_pdf_output, which will create a set of new restart files.

17 DETAILS OF FORTRAN SUBROUTINES & FUNCTIONS

Table 9 provides a list of all the Fortran subroutines developed as a part of the spray module. This table also provides information on all the Fortran functions. It also describes the purpose of all the individual subroutines and functions. Similarly, Table 10 provides a list of all the Fortran functions and subroutines associated with the implementation of the high pressure equation of state as described in Sec. 3, and the high pressure behavior on the gas-phase transport properties as in Sec.4.

18 DETAILS OF PARALLELIZATION

There are several issues associated with the parallelization of both the spray & PDF computations. The goal of the parallel implementation is to extract maximum parallelism so as to minimize the execution time for a given application on a specified number of processors [37]. Several types of overhead costs are associated with parallel implementation which include data dependency, communication, load imbalance, arithmetic, and memory overheads. The term arithmetic overhead is the extra arithmetic operations required by the parallel implementation. Memory overhead refers to the extra memory needed. Excessive memory overhead reduces the size of a problem that can be run on a given system and the other overheads result in performance degradation [37]. Any given application usually consists of several different phases that must be performed in certain sequential order. The degree of parallelism and data dependencies associated with each of the subtasks can vary widely [37]. The goal is to achieve maximum efficiency with a reasonable programming effort [37].

In our earlier work, we discussed the parallel implementation of a spray algorithm developed for the structured grid calculations on a Cray T3D [10]. These computations were performed in conjunction the Monte Carlo PDF method. The parallel algorithm made use of the shared memory constructs exclusive to Cray MPP (Massively Parallel Processing) Fortran and the computations showed a reasonable degree of parallel performance when they were performed on a NASA LeRC Cray T3D with the number of processors ranging between 8 to 32 [10]. Later on, the extension of this method to unstructured grids and parallel computing written in Fortran 77 with PVM or MPI calls was reported in [11-15]. The latest version in Fortran 77/90 offers greater computer platform independence. In this section, we only highlight some important aspects of parallelization from Refs. [10-15].

- Both the EUPDF and CFD modules are well suited for parallel implementation. For the gas-phase computations, the domain of computation is simply divided into n-Parts of nearly equal size and each part is solved by a different processor. Fig. 11a illustrates a simple example of the domain decomposition strategy adopted for the gas-phase computations where the total domain is simply divided equally amongst the available computer processing elements (PEs). In this case, we assumed the number of available PEs to be equal to four.

- But the spray computations are more difficult to parallelize for the reasons summarized below:
  1. Non-uniform nature of spray distribution: Most of the particles are usually confined to a small region where the atomizer is located.
  2. Dynamic nature of Lagrangian particles: Particles keep moving between different subdivided domains of an Eulerian grid (grid used in the CFD computation) which are assigned to different processors. While some new particles are introduced at the time of fuel injection, some others are taken out of computation.

  Conceptually, there are several ways to parallelize the spray computations, we, however, developed and tested two different domain decomposition strategies [10-14].

- **Strategy I:**
  The Lagrangian particles were assigned fairly uniform amongst the available processors but the calculations associated with the particle tracking, the interpolation of the gas-phase properties, and the source-term evaluation were computed on the processor of the computational grid in which a particle is located.

  This strategy leads to an uniform loading during integration but leads to excessive message passing.

- **Strategy II:**
  The Lagrangian particles were assigned to the processor of the computational grid where the particle is located. Fig. 11b illustrates a simple example of the domain decomposition strategy adopted for the liquid-phase computations where the corresponding gas-flow computational domain is divided into equal parts between the four available PEs. In this strategy, the Lagrangian particles are assigned to the processor.
of the computational grid where a particle is located.

This strategy leads to a non-uniform loading during integration but leads to less message passing.

Our experience has shown that Strategy II seems to work well on different computer platforms: both massively parallel computers as well as heterogeneous clusters of workstations. So in the present version of the code, we have opted to implement Strategy II over Strategy I.

19 DETAILS OF PARALLEL PERFORMANCE

The details of the combined parallel performance of the CFD, EUPDF, and LSPRAY codes involving several different cases can be found in Refs. [10-15]. Here, we only summarize briefly the parallel-performance results for two different cases. One is a 3D test case and more details on this case can be found in the reference [13]. For this case, the calculations were performed on a computational grid comprising of 8430 tetrahedral elements and 100 Monte Carlo PDF particles per cell. The computations were performed on one of the NASA Ames Research Center’s parallel computer platforms called Turing which is a SGI Origin work-station with 24 PEs (Processor Elements). Table 11 summarizes the CPU times per cycle taken by the EUPDF, LSPRAY, and CFD solvers vs the number of PEs. Both the CFD and PDF solvers show good parallel performance with an increase in the number of processors but for the spray solver it shows reasonable parallel performance.

Next, we would like to summarize the results from [13, 38] showing only the results of spray computations. The results are summarized in Table 12. The computations were performed on Turing at NASA ARC (Ames Research Center) - it is a SGI Origin work-station with a maximum of 24 PEs (Processor Elements). The computations made use of an unstructured grid with a mesh size of 3600 tetrahedral elements. And it made use of about 2,695 Lagrangian particles for the spray computations and one hundred Monte Carlo particles per element for the PDF computations. In a given cycle of one global time step, \( dt_{gl} \), the spray equations were advanced over one hundred time steps as given by \( dt_{gl}/dt_{mt} = 100 \). The first row of Table 12 summarizes the CPU times per PE per cycle taken by the spray solver vs the number of PEs. As expected, the CPU time goes down with an increase in the number of processors. In an ideal case, one would expect an inverse reduction in cpu time with an increase in the number of processors. Here, we don’t get such an ideal performance because of the resulting non-uniform distribution of spray particles, between various participating processors, from the implementation of Strategy II. To get an idea of the spray particle distribution, we have tabulated the maximum and minimum number of particles found between various processors. When we go from 1 to 2 PEs, 2097 particles are assigned to one and the rest to the second. With four they are distributed between 1165 and 118, with eight between 623 and 14, and with sixteen from 312 to 0. The results clearly show that the reduction in the CPU time varies almost linearly with the reduction in the number of maximum particles.

20 SUMMARY OF SOME VALIDATION CASES INVOLVING BOTH REACTING AND NON-REACTING SPRAY COMPUTATIONS

A total of the following nine cases were validated:

1. A reacting methanol spray with no-swirl,
2. A non-reacting methanol spray with no-swirl,
3. A confined swirl-stabilized n-heptane reacting spray,
4. An unconfined swirl-stabilized n-heptane reacting spray,
5. A confined swirl-stabilized kerosene reacting spray,
6. A flashing jet generated by the sudden release of pressurized R134A from cylindrical nozzle,
7. A liquid jet atomizing in a subsonic cross flow,
8. A Parker-Hannifin pressure swirl atomizer, &
9. A single-element LDI (Lean Direct Injector) combustor experiment.

The experimental data for the first two cases was provided by McDonell & Samuelsen from the University of California at Irvine [38]. Both the cases are without swirl; one is a reacting case and the other is non-reacting. The data for the third and fourth cases was provided by Bulzan from the NASA Glenn...
Research Center [39-40]. Both the cases are swirl-stabilized reacting cases, one is an unconfined flame and the other is confined. The data for the fifth case was provided by El Banhawy & Whitelaw from Imperial College [4]. It is a confined swirl-stabilized kerosene spray flame. Further details of the last four cases can be found in [78]. These cases were chosen because of their importance in some aerospace applications.

Here, we provide a brief summary of our validation effort but a detailed presentation of the results and discussion can be found elsewhere in the papers [10-13, 78]. The validation is based on some 3D and axisymmetric calculations involving both reacting and non-reacting sprays. Some of them were performed on unstructured grids and the others on structured grids.

The comparisons involved both gas and drop velocities, drop size distributions, drop spreading rates, and gas temperatures. In general, the predicted results provide reasonable agreement for both mean droplet sizes ($D_{32}$) and average droplet velocities but mostly underestimate the droplets sizes in the inner radial region of a cylindrical jet.

The comparisons also involved the results obtained from the use of the Monte Carlo PDF method as well as those obtained from a conventional CFD solution without the Monte Carlo PDF method. For the first case of McDonell & Samuelsen’s reacting spray flame, the detailed comparisons clearly highlighted the importance of chemistry/turbulence interactions in the modeling of reacting sprays [13]. The results from the PDF and non-PDF methods were found to be markedly different with the PDF solution providing a better approximation to the reported experimental data. The PDF solution showed that most of the combustion occurred in a predominantly diffusion-type of flame environment and the rest occurring in a predominantly premixed-type of flame environment. However, the non-PDF predictions showed incorrectly that most of the combustion occurred in a predominantly vaporization-controlled regime. The Monte Carlo temperature distribution showed that the functional form of the PDF for the temperature fluctuations varied substantially from point to point. The results brought to the fore some of the deficiencies associated with the use of assumed-shape PDF methods in spray computations.

• This manual provides a complete description of LSPRAY-V - a Lagrangian spray solver developed for application with parallel computing and unstructured grids.

• It facilitates the calculation of the multi-component liquid sprays with variable properties valid over a wide range of pressure conditions encountered in gas-turbine engines.

• It provides the user with a basic understanding of the spray formulation and the LSPRAY-V code structure, and complete details on how to couple the spray code to any other flow code.

• The basic structure adopted for the grid representation and parallelization for the gas side of the flow computations follows the guidelines established for NCC.

• Also, we have extended the joint scalar Monte Carlo PDF method to two-phase flows and, thereby, demonstrating the importance of chemistry/turbulence interactions in the modeling of reacting sprays.

• Based on the validation studies involving several confined and unconfined spray flames, the results were found to be encouraging in terms of their ability to capture the overall structure of a spray flame.

• The source code of LSPRAY-V will be available with OpenNCC as a complete package.
APPENDIX

DETAILS OF THE PRIMARY ATOMIZATION MODELS

1. Sheet Breakup Primary Atomization Model (Likely Application: Pressure Swirl Atomizer)

Here, we summarize the details of the sheet breakup model taken from Schmidt et al [48]. The growth of an infinitesimal disturbance as given by

\[ \eta = \eta_0 \exp(ikx + \omega t) \] (1)

was analyzed based on a linear stability analysis of a two-dimensional, viscous, incompressible liquid sheet of thickness 2h which moves through an inviscid, incompressible gas medium. This was analyzed in a coordinate system moving with the sheet with a relative velocity between the liquid and gas. Inviscid analysis also indicates that for low gas Weber number (\(We = \rho_g hU^2/\sigma\)) flows, long waves tend to grow leading to liquid sheet breakup but for higher Weber numbers, short waves produce a maximum growth rate followed by breakup. The critical Weber number that leads to the transition from the long wavelength regime to the short wavelength regime was shown to be \(We_g = 27/16\). For most modern fuel injection systems, the film Weber number is well above this critical limit. The growth rate for the sinusoidal mode, \(\omega_r\), based on an order of magnitude analysis of the dispersion relation yields,

\[ \omega_r = \frac{2\eta_k^2 \tanh(kh)}{\tanh(kh) + Q} \] (3)

For short waves in the limit of \(Q << 1\) for high-speed sheets, it yields

\[ \omega_r = -2\nu_k k^2 + \sqrt{4\nu_k^2 k^4 + QU^2 k^2 - \frac{\sigma k^3}{\rho_l}} \] (4)

Following Dombrowski & Johns [51], the sheet disintegration leads to the formation of ligaments once the unstable waves reach a critical amplitude and Eq. (4) shows that the growth rate of short waves is independent of the sheet thickness. The corresponding breakup time \(\tau\) and the breakup length \(L\) are given by:

\[ \eta_b = \eta_0 \exp(\Omega \tau) \Rightarrow \tau = \frac{1}{\Omega} \ln \frac{\eta_b}{\eta_0} \] (5)

\[ L = \frac{V \tau}{\Omega} = \frac{V}{\Omega} \ln \left( \frac{\eta_b}{\eta_0} \right) \] (6)

where \(\Omega\) is the maximum growth rate as determined by Eq. (4), the term \(\ln(\eta_b/\eta_0)\) has an assigned value of 12 as suggested by Dombrowski & Hooper [50], and \(V\) is the absolute velocity of the liquid.

The initial diameter of the ligaments is derived from a mass balance relationship. For long waves, it is assumed that the ligaments are formed from tears in the sheet once per wavelength and the resulting diameter is given by,

\[ d_L = \sqrt{\frac{8h}{K_{sb}}} \] (7)

where \(K_{sb}\) is the wave number corresponding to the maximum growth rate \(\Omega\) as obtained from Eq. (3) and the film thickness, \(h\), is calculated from the breakup length, \(L\), the radial distance from the centerline to the mid-line of the liquid sheet at the atomizer exit, \(r_o\), and the spray angle, \(\theta\), as follows:

\[ h = \frac{2\eta_k V L \sin(\theta/2)}{m} \]

For short waves, the ligament diameter is independent of the liquid sheet thickness and is assumed to be proportional to the wave length associated with the maximum growth rate \(\Omega\) as follows:

\[ d_L = \frac{2C_L}{K_{sb}} \]

For both long and short waves, Dombrowski & Johns [51] developed a linear stability analysis for the further breakup from ligaments to droplets based
on the Weber’s analysis on capillary instability. The analysis shows that the breakup occurs when the amplitude of the unstable waves exceeds the radius of the ligament. And the corresponding most unstable wavenumber, \( K_{lb} \), is given by:

\[
K_{lb}d_L = \left[ \frac{1}{2} + \frac{3 \mu_0}{2 \sqrt{\rho \sigma d_L}} \right]^{-\frac{1}{2}}
\]

(8)

This analysis thus yields the most probable droplet size based on a simple mass balance calculation where \( d_b^3 = \frac{3 \pi d_L^2}{K_{lb}} \).

### 1.1 Application to pressure swirl atomization

For the pressure swirl atomizer, the initial injector exit velocity and liquid sheet thickness are calculated following the approach of Schmidt et al [48]. It assumes a uniform velocity profile for the initial liquid velocity, \( V \), as given by,

\[
V = \max\{0.7, \frac{4 \dot{m}}{\pi d_o^2 \rho \cos \theta} \sqrt{\frac{\rho_l}{2 \Delta p}} \sqrt{\frac{\Delta p}{\rho_l}} \}
\]

(9)

where \( \dot{m} \) and \( \theta \) are the measured mass flow rate and spray angle, respectively, \( d_o \) is the injector exit diameter, and \( \Delta p \) is the pressure drop in the injector. Once \( V \) is known, the corresponding axial component of the sheet velocity is calculated via \( u = V \cos \theta \). And the initial sheet thickness \( h_o \) is calculated from the conservation of mass:

\[
\dot{m} = \pi \rho_l u h_o (d_o - h_o)
\]

(10)

At the point of primary breakup, the actual drop size is chosen from a Rosin-Rammler distribution with the mean size as given by \( d_o \) of the sheet breakup model. Further movement of the droplets is tracked by making use of a Lagrangian formulation.

### 2. Blob Jet Primary Atomization Model

(Likely Application: Single-Orifice Nozzles)

Here we summarize the details of the blob jet primary atomization model taken from Reitz & Bracco [41] and Reitz [52,45]. It applies for a cylindrical liquid jet issuing into an incompressible gas. The following dispersion relation was obtained based on the stability analysis of a cylindrical liquid surface subjected to linear perturbations:

\[
\omega^2 = \frac{2 \nu k^2 \sigma}{\nu l^2 (ka) I_1(k) I_0(k)} - \frac{2 k l}{k^2 + l^2} \frac{I_1(k)}{I_0(k) I_1(l)}
\]

\[
= \frac{\sigma k}{\rho_l a^2} \left( 1 - k^2 a^2 \right) \left( I_1(k) I_0(k) - I_1(l) I_0(l) \right)
\]

\[
+ \frac{\rho_g}{\rho_l} \left( U - i \omega k \right) \left( \frac{k^2 - l^2}{k^2 + l^2} \right) \frac{I_1(k) I_0(k) - I_1(l) I_0(l)}{I_0(k) I_1(l)}
\]

(11)

where \( I_0, I_1, \) and \( K_0, K_1 \) are the modified Bessel functions of the first and the second kinds.

Reitz [52,45] generated curve-fits of numerical solutions to Eq. (11) for the maximum growth rate \( \Omega (\omega = \Omega) \) and the corresponding wavelength \( \lambda = \Lambda \):

\[
\frac{\Lambda}{\alpha} = 9.02 \left( 1 + 0.45 \frac{Z^{0.5}}{l} + 0.45 \frac{l}{Z} \right)
\]

(12)

\[
\Omega \left( \frac{\alpha \Lambda}{\sigma} \right)^{0.5} = \frac{0.34 + 0.38 W e_g^{0.5}}{(1 + Z)(1 + 1.07 \frac{l}{Z})}
\]

(13)

where \( Z = W e_g^{0.5}, T = Z W e_g^{0.5}, W e_l = \frac{\rho_l U^2 a}{\sigma}, W e_g = \frac{\rho_g U^2 a}{\sigma}, \) and \( R e_l = \frac{U a}{l} \). A core region is predicted with the drop injection method because there is a region of large discrete liquid parcels near the nozzle. Based on the jet stability theory, new drops are formed from a parent drop or blob. It is assumed that small droplets (with radius, \( r \)) are formed from the parent drops (with radius, \( a \)) with drop size proportional to the wavelength of the fastest-growing or most-unstable wave,

\[
r = B_o a \quad \text{if} \quad B_o \Lambda \leq a\]

or

\[
r = \min \left\{ (3 \pi a^2 U/2 \Omega)^{0.33}, (3 a^2 / \Lambda^2)^{0.33} \right\}
\]

\[
\text{if} \quad B_o \Lambda > a, \text{ one time only}
\]

(14)

where \( B_o = 0.61 \) according to Reitz [52,45]. In the above, it is assumed for the \( (B_o \Lambda \leq a) \) condition that small droplets are formed with the drop size proportional to the wavelength of the fastest growing mode and the second \( (B_o \Lambda > a) \) condition applies to drops larger than the jet and it assumes that the jet disturbance has frequency \( \Omega/2\pi \) (a drop is formed each wave period) or that the drop size is determined from the volume of liquid contained under one surface wave. And the rate of change of droplet radius due to breakup is given by

\[
d a/dt = -(a - r)/\tau \quad (r \leq a)
\]

(15)

where \( \tau \) is the breakup time, \( \tau = 3.726 B_1 a / \Lambda \Omega \), and the value for the breakup time constant, \( B_1 \), depends on the injector characteristics and its value ranges between 1.732 to 40. And \( a(t = t_o) = a_o \) is the initial drop radius at time, \( t_o \).
After the breakup, a new parcel containing product drops of size, \( r \), is created and added to the computations. This was done as long as the mass of the liquid removed from the parent \((\rho_l 4\pi (a_0^3 - a^3)/3)\) reached or exceeded 3% of the average injected parcel mass and if the number of product drops is greater than or equal to the number of parent drops [45]. While waiting for sufficient product drops to accumulate, the parent drop number was adjusted so that \( N_a^3 = N_o a_o^3 \) but the parent drop number, \( N_o \), was then restored following the creation of the new product parcel [45].

In the case of \((B_o A > a)\), the parent parcel was replaced by a new parcel containing drops with size given by Eq. 14 after a time equal to \( \tau \) (with \( N = N_o a_o^3/r^3 \)) [45]. This breakup procedure was allowed only once for each injected parcel [45].

Validation of the model for a single hole orifice in a typical diesel engine was demonstrated by Reitz and Diwaker [46] and Reitz [52, 45].

3. Air Blast Primary Atomization Model
(Likely Application: Air Blast Atomizers)

The air blast atomization model is essentially based on the idea of pressure-swirl atomization model (Section 1.1) as the primary atomization of an air blast injector is based on the aerodynamic analysis involving the Kelvin-Helmholtz instability of a liquid jet in an incompressible gas. It, however, differs from the pressure-swirl atomization model in the determination of the initial sheet velocity and thickness, which are given by

\[
V_{\text{sheet}} = \alpha V_l + (1-\alpha)V_g
\]

\[
\delta = r\left[1 - \sqrt{1 - \frac{\dot{m}}{\pi r^2 \rho V_{\text{sheet}}}}\right]
\]

where \( \alpha \) has a value of 0.12 to 1 depending on the fuel filmer characteristics, \( r \) is the radius of the fuel filmer, and \( \dot{m} \) is the fuel flow rate. The continuous annular sheet is represented by a finite number of point injectors located randomly along the circular ring of the liquid sheet.

4. Modified BLS Primary Atomization Model
(Likely Application: Liquid Jet in a Cross Flow)

Here we summarize the details of the BLS atomization model taken from Khosla and Crocker [47]. In this model both surface shear breakup and column breakup modes are included. Before column breakup, fragments may be formed due to boundary layer stripping depending on the local Weber number and \( q = (\rho_l u_l^2/\rho_g u_g^2) \). When the jet reaches the column breakup time, the entire jet breaks into fragments. It also allows for further breakup of the fragments based on a modified boundary layer stripping. And it is followed by a final breakup step based on the Rayleigh-Taylor secondary droplet breakup model.

Fragments are stripped from the liquid column if the \( We_g \) satisfies the following criteria:

\[
We_g > 50Re_g^{1/2} q^{-1/0.81} \quad \text{and} \quad We_g > 15
\]

where

\[
Re_g = \rho_g d_j u_g/\mu_g
\]

\[
we_g = u_l^2 d_j \rho_g/\sigma_l
\]

where \( Re_g \) and \( We_g \) are based on the gas velocity component normal to the liquid jet direction instead of the relative velocity. If column stripping does occur, the amount of mass removed from the column is given by

\[
M_{\text{shed}} = \frac{3}{4} \pi d_j t_b u_{\text{rel}} A \sqrt{\frac{\pi d}{4}} \Delta t
\]

where,

\[
A = \left[\frac{\rho_l}{\rho_g}\right]^{1/3} \left[\frac{\mu_g}{\mu_l}\right]^{1/3}
\]

\[
\alpha = \left[\frac{8 \mu_l}{3 A u_{\text{rel}} \rho_l}\right]^{1/2}
\]

\[
t^* = \frac{d_j \sqrt{\frac{\mu}{\rho_g}}}{u_g}
\]

where \( t_b \) is the liquid column drop lifetime. The addition of the factor \( t^*/t_b \) causes the shedding rate to increase essentially linearly with distance away from the injection location. This accounts for the lack of shedding close to the injection location and the subsequent buildup of shedding over the life of the liquid column. The shed drop SMD (Sauter Mean Diameter) is given by
The $t_b/t^*$ factor is included with the effect of producing smaller drops near the injection location. However, $t_b/t^*$ is limited to a minimum value of 2.5 which is never exceeded for some cases. The amount of mass shed is tracked and 10 new parcels are created when the cumulative shed mass after a time step exceeds 1% of the mass of the parcel. Each parcel is allocated an equal amount of the shed mass and the size for each new parcel is selected randomly from a uniform distribution between 0.4 and 1.6 times the mass mean diameter, MMD. And the drop velocities were given by

$$u_d = u_p + 0.3(RND - 0.2)(u_g - u_p)$$  \hspace{1cm} (24)$$

$$v_d = v_p + 0.3(RND - 0.2)(v_g - v_p)$$ \hspace{1cm} (25)$$

$$w_d = w_p + 0.25(RND - 0.5)(u_{rel} - w_p)$$ \hspace{1cm} (26)$$

where $RND$ is a random number. Column stripping occurs, assuming the above criteria are met, until the column breakup time is exceeded. Parcels created through the column stripping mechanism are considered to be fragments which may undergo further breakup as discussed below. First, though, the column breakup mechanism, which also produces fragments, is described. The liquid jet column breakup time is given by

$$t_b = A_b We^{0.02} t^*$$ \hspace{1cm} (27)$$

The constant, $A_b$, has a value of 25. Since the present model includes a fragment breakup step after the column breakup, the $We$ dependence for the breakup onset was retained.

After the column breakup time is reached, the column is broken into 18 new parcels with $MMD = 0.45d_j$. The new parcels are also designated as fragments. The size of the fragments still tend to be large, so the ultimate drop size from the primary breakup process is mostly determined from the fragment breakup process. The size distribution is the same as described above for the column stripping. The cross flow and normal velocity components are the same as Eqs. (24) and (25). The lateral velocity component is given by

$$w_d = w_p + 0.1(RND - 0.5)(u_{rel} - w_p)$$ \hspace{1cm} (28)$$

Fragments are further broken into small drops according to a modified version of the boundary layer stripping model based on the following criteria,

$$We_g > \sqrt{Re}$$ and $$We_g > 15$$ \hspace{1cm} (29)$$

where

$$we_g = \frac{u_{rel} d_d \rho_g}{\sigma_l}$$

$$Re_g = \frac{\rho_g d_d u_{rel}}{\mu_g}$$

The criteria are generally the same as for column stripping except that the dependence on $q$ is not needed. Also note that $We$ and $Re$ are now determined using the relative velocity instead of the cross flow velocity. Again, the mass shed from a fragment in a time step and the SMD are given by

$$M_{shed} = 1.2\pi d_l u_{rel} A a \sqrt{\frac{\pi d^2}{4} \Delta t}$$ \hspace{1cm} (30)$$

$$SMD = 3.6 d^{1/2} \left[ \frac{\rho_l}{\rho_g} \right]^{1/4} \left[ \frac{\mu_l}{u_{rel} \rho_l} \right]^{1/2}$$ \hspace{1cm} (31)$$

where $A$ and $a$ are given by Eqs. (20) and (21), respectively. The new droplet velocities are given by Eqs. (24), (25), and (28). The broken fragments produce 3 new parcels with size distribution the same as described above when the shed mass from the fragment exceeds 20% of the fragment mass. A fragment can continue to breakup until it no longer meets the criteria of Eq. (29) or until its size is lower than the newly created drops. Once the fragment breakup process is complete, drops may breakup further based on a Rayleigh-Taylor secondary breakup method.

Khosla and Crocker [47] applied the model to predict the properties of Jet A-1 kerosene fuel injected into a cross-flowing air stream.
DETAILS OF THE SECONDARY DROPLET BREAKUP MODELS

Recent studies by Reitz et al. [55, 52] have examined the breakup of single droplets moving in a transverse, high-velocity air jet. The high-speed photography provided new insights into the details of the breakup mechanism of a single drop. The droplet breakup regimes are classified as bag, stripping (shear) and catastrophic (surface wave) based on an increasing size of Weber number. In the bag breakup mode (at low Weber number), the drop is flattened by the aerodynamic pressure, then turned inside out, forming a thin hollow bag which is tied together with a circular belt-like structure on the windward side. The bag eventually bursts into smaller liquid fragments, whereas the belt decays into larger ligaments and droplets. In the stripping regime thin sheets or ligaments of fluid are continuously shed from the periphery of the distorting parent drop as a consequence of a K-H instability, causing these sheets to disintegrate into tiny droplets. This process always leaves a coherent residual parent drop. The catastrophic drop breakup takes place in two stages leading to a collection of larger and tiny product droplets: Large amplitude long-wavelength waves caused by drop deceleration induce a R-T instability on the flattened drop which leads to a breakup into large product droplets, while at the same time short surface waves induce a K-H instability on the windward side of the parent drop resulting in a collection of much smaller product droplets. In diesel or other high-pressure gas-turbine sprays the droplets span a wide range of velocities and hence Weber numbers, and thus it is expected that all three droplet breakup mechanisms are relevant in the breakup modeling.

In what follows, we provide some details of the secondary droplet breakup models contained in the CFDRC/UW atomization module: (1) Rayleigh-Taylor, (2) TAB, and (3) ETAB. These details are taken from [52-56, 42-44].

1. Rayleigh-Taylor Secondary Droplet Breakup Model

Here we summarize the Rayleigh-Taylor secondary breakup model developed by Patterson and Reitz [57]. It is based on the analysis developed by Taylor [53, 57] that accounts for the disturbances caused by droplet deceleration. In the Rayleigh-Taylor breakup mechanism, the breakup wavelength, $\Lambda$, is given by

$$\Lambda = 0.2\pi \sqrt{\frac{3\sigma}{|\dot{u}_d|}}\left(\frac{\rho_l - \rho_g}{\rho_l g}\right)$$  \hspace{1cm} (32)

where $\dot{u}_d$ is the drop deceleration ($= \frac{3c_d\rho_l U^2}{\rho_g d}$, $c_d$ is the aerodynamic drag coefficient, $U$ is the drop relative velocity, $\&$ $d$ is the drop diameter). Furthermore, the breakup wavelength $\Lambda$ is limited by

$$\Lambda = \max(0.8d, \Lambda)[1 + 0.2(RND - 0.5)]$$  \hspace{1cm} (33)

and the breakup time, $t_{b,RT}$, is given by

$$t_{b,RT} = c_{freq} \sqrt{0.5\sqrt{\sigma}(\rho_l + \rho_g)\left(\frac{3}{|\dot{u}_d|}(\rho_l - \rho_g)\right)^{1.5}}$$  \hspace{1cm} (34)

However, the value assigned for the constant, $c_{freq}$, depends on the droplet classification - parent, product, or default. For more details, one can refer to Patterson and Reitz [21]. After the breakup, no new drop parcels are created and there is no change in velocities between the parent and product drops. However, the drop number in a given parcel changes to $n_{product}$ as given by $n_{parent}(d_{parent}/\Lambda)^3$ due to the change in the sizes between the parent and product drops.

2. The TAB Secondary Droplet Breakup Model (Likely Application:
Lenticular-Shaped Droplet Deformations)

In an attempt to provide a description of the droplet and jet disintegration in the modeling of diesel sprays, O’Rourke & Amsden introduced the TAB model [42]. Here we summarize the TAB model taken from [43-44].

The TAB breakup model is based on Taylor's analogy between an oscillating, distorting drop and a spring-mass system. A detailed analysis of this model together with a discussion of its numerical implementation can be found in [42 & 58]. In this model, the drop motion is governed by a linear ordinary differential equation for a forced, damped harmonic oscillator. The forcing term is given by the aerodynamic droplet-gas interaction, the damping is due to the liquid viscosity and the restoring force is supplied by the surface tension. The parameters and constants have been determined partly from theoretical considerations and partly from experimental observations.

The TAB model describes the distortion of the drop by the deformation parameter, $y = 2x/a$, where $x$ denotes the increase in the radius increase of the equator from its equilibrium position and $a$...
is the drop radius. The equation for the distortion parameter \( y \) is given by

\[
\ddot{y} + \frac{5\mu_y}{\rho a^2} \dot{y} + \frac{8\sigma}{\rho a^3} y = \frac{2\rho a|U|^2}{3\rho a^2} \tag{35}
\]

Assuming a constant relative drop-gas velocity, \( U \) (which is satisfied in the numerical solution process during a given time step), the solution to Eq. (35) is given by

\[
y(t) = \frac{We}{12} + e^{\frac{\omega}{\omega_d}} ([y(0) - \frac{We}{12}] \cos \omega t
\]
\[+ \left( \frac{\dot{y}}{\omega} + \frac{y(0) - \frac{We}{12}}{\omega_d} \right) \sin \omega t \tag{36}\]

where \( We = \rho a U^2/\sigma \) and

\[
t_d = \frac{2\rho a^2}{5\mu_y} \tag{37}
\]
\[
\omega^2 = \frac{8\sigma}{\rho a^3} - \frac{1}{t_d^2} \tag{38}
\]

In this model, it is assumed that a necessary condition for drop breakup is reached when \( We > We_{crit} \). And the value for the critical Weber number is determined experimentally to be 6. For an inviscid liquid with initial deformation conditions \( y(0) = \dot{y}(0) = 0 \), the solution to Eq. (35) reduces to \( y(t) = \frac{We}{12}(1 - \cos \omega_d t) \), where \( \omega_d = \frac{8\sigma}{\rho a^3} \) [44]. Consequently, the breakup occurs when \( y(t) > 1 \). The drop size after breakup is determined by an energy balance equation between the parent and the product droplets which equates the surface energies of parent drops with the energies of product drops due to oscillation and distortion. Also, the product droplets are initially equipped with the additional deformation velocity \( \dot{x} = \frac{\alpha \dot{y}}{2} \), which acts normal to the path of the parent drop and is responsible for the formation of the spray angle.

One major advantage of this model is that it is based on a simple linear equation and it can be used effectively to describe the lenticular-shaped droplet deformations as observed in the experiments of [56 & 54].

3. The ETAB Secondary Droplet Breakup Model (Likely Application: High-Pressure Diesel Engine)

Here we provide some details of the ETAB model taken from Tanner [43-44]. The ETAB model is based on the following modifications to the standard TAB model: (1) the droplet disintegration is modeled via an exponential law which relates the mean product droplet size to the breakup time of the parent drop; and (2) an energy balance consideration between the parent and product droplets yields an expression for the normal velocity component of the product droplet.

When the breakup condition of \( We > We_{crit} = 6 \) and \( y(t) = 1 \) is met, then the parent drop breaks up into a collection of product droplets, subject to a size distribution function which, in general, depends on the breakup mechanism. In the ETAB model, the rate of product droplet generation, \( dn(t)/dt \), is given by

\[
\frac{dn(t)}{dt} = 3K_b n(t) \tag{39}
\]

where \( n(t) = \frac{m_0}{\bar{m}_t} \) and \( m_0 \) is the mass of the parent drop and \( \bar{m}_t \) the mean mass of the product droplet distribution. Utilizing the fact that \( \frac{dn}{dt} = -\frac{m_0}{\bar{m}_t}(\frac{dn}{dt}) \), leads to the breakup law which relates the product drop size to the breakup time as determined by the TAB model.

\[
\frac{d\bar{m}_t}{dt} = -3K_b \bar{m}_t \tag{40}
\]

The breakup constant \( K_b \) depends on the breakup regime and is given by parent drop properties only. Bag breakup occurs if \( We = We_t \) and stripping breakup happens if \( We > We_t \). And it is given by

\[
K_b = \begin{cases} k_1 \omega & \text{if } We \leq We_t \\
\sqrt{\frac{2\omega}{We}} & \text{if } We > We_t \end{cases} \tag{41}
\]

The values for \( We_t \), \( k_1 \) and \( k_2 \) have been determined experimentally and has been set to \( k_1 \approx 1/4.5 \) and \( We_t = 80 \).

In this model, a uniform product droplet size distribution is assumed. It is also noted that the choice of uniform distribution is not expected to be realistic but may produce good approximations when averaged over many drop breakups, because parent drops of different sizes and Weber numbers will in general yield a wide range of duct droplet sizes. With this assumption, Eq. (40) becomes

\[
\frac{r}{a} = e^{-K_b t} \tag{42}
\]
where $a$ and $r$ are the radii of the parent and product drops, respectively.

After breakup of a parent drop, the initial deformation parameters of the product droplets are set to $y(0) = \dot{y}(0) = 0$. Also, the product droplets are initially supplied with a velocity component perpendicular to the path of the parent drop with a value $v_T = A\dot{x}$, where $A$ is a constant determined from the following energy balance consideration. The energy of the parent drop is the sum of the surface tension energy and the droplet deformation energy. The second is computed as the product of the aerodynamic drag and the drop deformation at the stagnation point, estimated to be $5a/9$. This leads to

$$E_{\text{parent}} = 4\pi \sigma a^2 + 5\pi c_d \rho g a^3 \frac{|U|^2}{18} \quad (43)$$

And the energy of the product droplets in the frame of reference of the parent drop is given by

$$E_{\text{product}} = 4\pi \sigma a^3/r_{\text{SMR}} + A^2 \pi \rho a^5 \frac{\dot{y}^2}{6} \quad (44)$$

where the Sauter mean radius, $r_{\text{SMR}}$, enters via the relation $\bar{r}^2 = \frac{a^3}{r_{\text{SMR}}}$. From Eqs. (43) and (44) one obtains the relation

$$A^2 = 3[1 - \frac{a}{r_{\text{SMR}}} + 5c_d \frac{Wei}{72}]\frac{\omega^2}{\dot{y}^2} \quad (45)$$

where $\omega^2 = \frac{8\sigma}{\rho \alpha_7}$.

Tanner [43-44] analysis yields an approximate value of 0.69 for $A$ showing that only 70% of the parent drop deformation velocity goes into the normal velocity component of the product droplets, whereas it is 100% in the standard TAB model.

Also, the characteristic time, $\tau (= \frac{1}{K_1})$, for breakup in Eq. (42) for an inviscid liquid ($\mu_1 = 0$) is given by $\alpha_1 \sqrt{\frac{\rho a^2}{\sigma}}$ if $Wei \leq Wei$, or $\alpha_2 \sqrt{\frac{\rho g a}{\rho g |U|}}$ if $Wei > Wei$, where the suggested values are for $\alpha_1 = (\sqrt{3k_1})^{-1}$ and $\alpha_2 = (\sqrt{8k_2})^{-1}$.

The application of the ETAB model in the simulation of a high pressure liquid jet breakup can be found in [43-44].
