ABSTRACT

The objective of this project was to conduct additive manufacturing to produce aircraft engine components by Fused Deposition Modeling (FDM), using commercially available polyetherimides – Ultem 9085 and experimental Ultem 1000 mixed with 10% chopped carbon fiber. A property comparison between FDM-printed and injection-molded coupons for Ultem 9085, Ultem 1000 resin and the fiber-filled composite Ultem 1000 was carried out. Furthermore, an acoustic liner was printed from Ultem 9085 simulating conventional honeycomb structured liners and tested in a wind tunnel. Composite compressor inlet guide vanes were also printed using fiber-filled Ultem 1000 filaments and tested in a cascade rig. The fiber-filled Ultem 1000 filaments and composite vanes were characterized by scanning electron microscope (SEM) and acid digestion to determine the porosity of FDM-printed articles which ranged from 25-31%. Coupons of Ultem 9085 and experimental Ultem 1000 composites were tested at room temperature and 400°F to evaluate their corresponding mechanical properties.

1. INTRODUCTION

Additive manufacturing (AM) has gained considerable attention recently, because of the promise of being able to produce net shape 3D components layer by layer directly by automated machines. This is especially true for complex shape polymer parts and low production volume components, which are not economical to produce by injection molding. In addition, AM offers quick turn- around time for specialty parts and shortened production and testing cycle for components. This project concentrated on Fused Deposition Modeling (FDM) technique (Fig. 1) in which a polymer filament is melted and then deposited in successive layers to build a 3D component according to a computer-aided design (CAD) file [1]. The state-of-the art of FDM are populated with commercial ABS (acrylonitrile butadiene styrene), polycarbonate [2] and polyamides such as Nylons for use as prototyping at the temperature around 100-125 °C (212-257° F).
The objective of the project was to develop additive manufacturing approaches for polymeric aircraft engine components and conduct testing on coupons as well as built parts, such as acoustic testing in a wind tunnel. The Ultem 9085 polyetherimide filament is one of the commercial polymers marketed by Stratasys for use in FDM with a glass transition temperature ($T_g$) of 186 °C (367 °F). Ultem 9085 is certified by FAA as flame retardant polymer for use in aircraft cabin. This project used Ultem 9085 as the baseline polymer for printing demonstration components, such as acoustic liners and a perforated engine access door. Furthermore, this project also strived to advance the FDM process into building polymer composites for aircraft engine parts. These additively manufactured components were tested in rigs and results have been presented in the first part of the report [3]. The Ultem 1000 with 10% AS4 carbon fiber was chosen as the candidate fiber-filled polymer filaments for this project, because Stratasys is making it available for the first time as an experimental filament under the State funded Ohio Third Frontier research project. Ultem 1000 is a homopolymer with higher $T_g$ (217 °C, 423 °F) than that of Ultem 9085 which is a blend of polycarbonate and Ultem 1000 with lower viscosity and cost suitable for injection molding.

2. EXPERIMENTATION

All the FDM printing was performed at Rapid Prototype Plus Manufacturing (rp+m), using Stratasys’ open source Fortus 400mc or 900mc FDM machines. The experimental XH6050 resin and carbon-fiber-filled Ultem 1000 filaments were supplied by Stratasys under the Ohio Third Frontier Program — Advanced Materials for Additive Manufacturing Maturation. The Ultem resins and composites were printed between 375-420 °C (707-788 °F). The specific engine components were selected by Honeywell Aerospace. Using Ultem 9085, a perforated engine door (Fig. 2a), an acoustic liner and its demonstration components (Fig. 2b) with 93 °C (200 °F) use temperature were printed by FDM at 375 °C in one piece, simulating the Aramid honeycomb structures bonded with epoxy composite face sheet. Additionally, composite vanes (Fig. 2c) with use temperature up to 204 °C (400°F) were printed at 420 °C, using Ultem 1000 filled with 10% chopped AS4 carbon fibers. Rig testing conditions and results of acoustic liner and composite inlet guide vane (IGV) are described in details in the first part of the report [3].
3. RESULTS AND DISCUSSION

3.1 Property Comparison of FDM and Injection Molding

A mechanical property comparison between FDM-printed and injection-molded coupons of Ultem 9085, Ultem 1000 and the carbon-fiber-filled Ultem 1000 are shown in Table 1. These data indicated that Ultem 9085 (printed at 0° raster angle), displayed about 87% of tensile strength and 64% of modulus, as compared to the injection molded counter parts, due to the presence of inherent porosities within the FDM-printed test coupons. The porosity of FDM-printed Ultem 9085 was about 5-8%, depending on the orientation of the layup. The mechanical strength of FDM generated specimens also relied on the built direction, the thickness of the filaments, the tool path generation and the air gap between raster in the filled pattern. In general, the FDM generated structures are more brittle and have lower elongation than the injection molded counterparts [4].

3.2 Initial Characterization of Carbon Fiber Filled Ultem 1000 Composites and Filaments

The initial tensile strength of 10% AS4 fiber-filled Ultem 1000 composites (first batch ever made from Stratasys) was only about 70% of Ultem 9085 resin as printed by FDM (Fig. 3), which was much lower than expected. The printing of ±45° raster angle reduced the strength by 80-86% as opposed to 0°. Further investigation by acid digestion indicated that the porosity of fiber-filler Ultem 1000 vanes ranged from 23-26%, which are unusually high (Table 2). The printing orientation did not exhibit much difference in terms of porosity. However, the porosity measurement based on the integration of optical microscope images (Fig. 4) ranged from 29-34% (Table 3), which was even higher than the 23-26% porosity obtained by acid digestion.

To understand the origin of high porosity in the FDM-printed fiber-filled Ultem 1000 composites, an effort was initiated to investigate the as-received thick Ultem 1000 filament filled with 10% chopped AS4 carbon fibers, which was fed into the FDM machine. The fiber-filled Ultem 1000 filaments were produced by mixing 6 mm AS4 chopped fibers with Ultem 1000 in an extruder, cut into pellets, and then re-extruded into filaments at Stratasys. As shown in Fig. 5, the longitudinal section (a) revealed that the chopped fibers were aligned with the filament axis, and significant amounts of the fibers were further chopped into average length of 2-3 mm during the extrusion process. The cross section (b-e) indicated that there were little voids present in the as-received filaments in this segment of initial investigation.
Figure 5. Photomicrographs of 10% AS4 fiber filled Ultem 1000 filaments (as received-thick)

Separately, thin filaments of fiber-filled Ultem 1000 extruded from the liquefier of Stratasys’ Fortus 400mc FDM machine at 420 °C were collected and analyzed, since these thin filaments were used directly for FDM printing. As shown in Fig. 6, the FDM extruded thin filaments were full of voids in the form of blisters, due to the sudden exposure to extreme high heat.

Figure 6. Photomicrographs of 10% AS4 fiber filled Ultem 1000 filaments (thin)

The acid digestion values in Table 4 confirmed that this segment of as-received thick fiber-filled filament analyzed had no porosity as confirmed by the photomicrographs in Fig. 5. The fiber content was 9% by weight which was very close to the original formulation of 10% chopped fibers. However, the thin FDM-extruded filaments were found to have about 31% of porosity, which was closer to the image analysis result of 33% porosity than that of 24-26% porosity by acid digestion of the printed vane.

* Thick filament—as received and fed into FDM machine; thin filament—extruded from FDM machine

Thermogravimetric analysis (TGA) with Fourier Transform Infrared Spectroscopy (FTIR) was carried out to investigate the origin of blistering in Ultem 1000. As shown in Fig. 7, the major weight loss shown in TGA up to 300 °C (572 °F) corresponded to water shown in FTIR, which indicated that some water was trapped inside the filament, which was more difficult to remove than the surface water. Additionally, Fig. 8 indicated that Ultem 1000 resin pellet contained 0.375% of water, and the fiber-filled Ultem 1000 filament had 0.593% of water whereas separate TGA analysis had indicated that the chopped fiber contained 0.25% of water. These two curves indicated that other than water loss, the Ultem resin and filament are very stable until about 500 °C (932 °F). However, the thin fiber-filled filament showed not only the loss of surface water around 100 °C (212 °F), but also some other weight loss due to degradation, as it had been exposed to the sudden high temperature of 420 °C (788 °F) at the liquefier in the FDM machine during the melting process. This first lot of the fiber-filled Ultem 1000 filament seemed to be solid but brittle whereas the thin filament appeared to be fragile and extremely porous.

![Figure 7. TGA-FTIR analysis of the fiber-filled Ultem 1000 filament](image-url)
3. 3 Evaluation of Drying Processes for Fiber-Filled Ultem 1000 Filaments

1) To improve the quality and mechanical properties of FDM-printed composites, an initial drying of as-received filament at 185 °C (365 °F) was carried out to remove the water from fiber-filled Ultem 1000 in an air-circulation oven for 12 hours; this was followed by the printing two cubes by FDM (Fig. 9). The dried thick filaments and FDM-spun thin fibers seemed shrunken and more ductile than the corresponding as-received filaments and un-dried FDM-spun thin filaments. The resulting printed cubes contained much lower porosity (13.6-17.4%) than that of the vanes (23-26%) as indicted in Table 2.

2) A second drying trial for fiber-filled Ultem 1000 was conducted at 204 °C (400 °F) for 22 hours. SEM micrographs in Fig. 10 showed that the dried thick filaments still had large pores of voids which were formed by the trapped water, air or other gases within the filaments during extrusion and drying (Fig. 10a), as well as the small pores of fiber pull-out at the fracture surface. Furthermore, Fig. 10b revealed that the porosity of FDM-spun thin filaments was much higher than the thick filaments as confirmed by acid digestion values listed in Table 5. The severe porosity of thin filaments were the results of volume expansion of trapped water vapors, air bubbles or other gases generated from the degradation of Ultem 1000 resin exposed to the sudden high liquefying temperature of 420 °C (788 °F) used to spin it within the FDM machine.

3) A third drying process was conducted in a desiccant system at 149 °C (300 °F) for 12 hours and characterized along with another section of as-received thick carbon-filled Ultem 1000 filaments as a repeat to investigate the uniformity and porosity of the experimental composite filaments supplied by Stratasys. As shown in Table 5, the porosity of the fiber-filled Ultem 1000 thick filaments as-received for the second trial was 15.3% which is much higher than the void-free in the initial as-received filaments. This clearly indicated that the porosity of experimental fiber-filled Ultem 1000 filaments varied considerably from 0-15.3%, and the porosity remained at 15% even after drying at 149 °C for 12 hours (Fig. 11). The photomicrographs in Fig. 10 also confirmed that as-received fiber-filled Ultem 1000 filaments exhibited some porosity this time, in contrast to the void-free segment shown in Fig. 4 previously. Since the moisture content of the as-received Ultem 1000 composite filaments was only 0.6 %, including 0.2 % moisture from as-received chopped fibers, the voids shown in the as-received fiber-filled Ultem 1000 thick filaments could either come from moisture trapped inside or the air bubbles introduced during the extrusion process. Nevertheless, after drying at various conditions, all the FDM-extruded thin filaments still displayed consistent porosity of ~25%, which is similar to porosity of printed composite vanes, but lower than the 30% porosity detected in the FDM-extruded thin filaments derived from the undried thick filaments (Table 5). This fact clearly indicated that once the moisture pore or air bubbles formed within the filaments, they are much more difficult to remove than the surface water.

**3.4 Mechanical Properties of FDM-Printed Ultem Resin and Ultem 1000 Composites**

Tensile tests of FDM-printed Ultem 9085, Ultem 1000, XH6050 and fiber-filled Ultem 1000 coupons were conducted at room temperature and 204 °C (400 °F) as listed in Table 6. Fig. 12 showed that Ultem 1000/C-fiber composite printed with the dried FDM filament showed the highest modulus while Ultem 9085 resin showed the highest toughness and strength at room temperature. The carbon fiber reinforcement Ultem 1000 was estimated to increase the tensile strength by 23% and modulus by 38% while the strain-to-failure ration dropped by 55%, back-
calculated based on XH6050 data of injection-molded versus FDM-printed. Regardless of test temperature, Ultem XH6050 showed inferior properties than either Ultem 1000 composites or Ultem 9085 \(T_g = 186 \, ^\circ C\), despite of its higher \(T_g = 245 \, ^\circ C\). XH6050 also showed significant losses in toughness and strength at 204 \( ^\circ C (400 \, ^\circ F)\). Thermal analysis results in Table 7 showed that substantial moisture still trapped within the composites even after drying.

More specifically, drying FDM filament prior to FDM-printing improved the room temperature (RT) properties of Ultem 1000 composites considerably, as indicated by the reduced porosities of FDM-extruded thin filaments from 30% to 24% after various drying conditions (Table 5), especially ±45° samples, even though its residual moisture content was still high. As shown in Fig.13, the 0° sample, showed ~ 8% increase in modulus, ~ 3% increase in strength, but ~ 11% decrease in strain-to-failure. The ±45° sample displayed ~26% increase in modulus, ~ 20% increase in strength, but ~ 2.4% decrease in strain-to-failure. At 204°C which is near Ultem1000’s Tg (217°C), all the properties decreased considerably due to the softening of the resin.

3.5 Characterization of Ultem 9085 versus Ultem 1000

An effort was undertaken to understand why FDM-printed fiber-filled Ultem 1000 composites exhibited an average of 25% porosity whereas Ultem 9085 displayed only 5-8% porosity associated with the inherent FDM process. Acid digestion of the as-received Ultem 9085 neat resin filaments showed 1.8-3.5% porosity and optical micrograms in Fig. 14 indicated that both as-received Ultem 9085 filaments and thin filaments extruded at 375 °C by FDM exhibited no porosity. The discrepancy between two methods depends on the segments of the filaments analyzed in each technique, and subjected to variable porosity. Thermal analysis of Ultem 9085 revealed that there was 0.3-0.4 % weight loss between 100-300 °C due to moisture presence in the as received filaments, which is common among all the moisture sensitive polyetherimides.

Figure 14. Optical micrographs of Ultem 9085 resin filaments

As shown in Fig. 15, the complex viscosity of Ultem 1000 is ~3 fold higher than that of Ultem 9085 at 350 °C. Basically, the high viscosity of Ultem 1000 raised the printing temperature of fiber-filled Ultem 1000 to 420°C, causing the volume expansion of trapped moisture and degradation gases, which in terms increased the porosity of the FDM product, as compared to Ultem 9085 that generally printed at 375 °C with lower porosity (5-8%). The as-received fiber-filled Ultem 1000 composite filaments with varied porosity of 0-15% clearly warranted more process improvement. One possible solution is to produce Ultem 1000 with controlled molecular weight that exhibits similar viscosity profile as that of Ultem 9085 to enable printing at 375-380 °C; thus, avoiding polymer degradation and ensuring production of high quality 3D objects with low porosity.

4. CONCLUSIONS

To advance the state-of-the-art in additive manufacturing via Fused Deposition Modeling (FDM) beyond the commonly used ABS, polycarbonate and Nylons as prototyping for 100-125 °C use, this project aimed at producing aircraft engine components by FDM, using Ultem 9085 and carbon fiber-filled Ultem 1000 composite filaments with higher temperature (130-175 °C) capability.

A perforated access engine door and acoustic liners, simulating conventional honeycomb structures, were printed with Ultem 9085 to modulate the sound wave and reduce noises. Composite engine inlet guide vanes were printed using Ultem 1000 filled with 10% AS4 chopped fibers as a reinforcement to eliminate the need for machining when using conventional polymer prepregs to make vanes. Preliminary data indicated that the FDM-printed Ultem 9085 exhibited about 84% of its original strength and 64% of its original modulus as compared to its injection-molded counter parts. The incorporation of 10% chopped fiber into Ultem 1000 increased the tensile strength by 23% and modulus by 38%, but also made the resulting composites more brittle. The experimental fiber-filled Ultem 1000 filaments (as received) contained 0-15% varied porosity. However, the FDM extruded thin filaments and FDM printed Ultem 1000 composite vanes exhibited ~25% porosity, due to the volume expansion of trapped moisture, air or other gases generated form degradation at elevated printing temperature of 420 °C by FDM. In contrast, the Ultem 9085 resin filament is a high quality commercial product that manufactures 3D objects with only 5-8% porosity inherently associated with the FDM process when printed at 375 °C.
In summary, this project proved the feasibility of printing integrated complex aircraft parts with polymers by FDM. FDM printing compared favorable to bonded honeycomb structures with face sheets in acoustic liners. However, printing composite parts by FDM is still considered experimental, as in the case of this effort to print Ultem 1000 composite vanes. Incorporation of 10% of chopped fibers into Ultem 1000 raised the viscosity significantly that affected the compounding efficiency in the extruder, resulting in high porosity in the extruded filaments and FDM-printed composite objects. In light of conventional polymer composites with 65% fiber content, additive manufacturing only looks favorable for printing intricate parts that are difficult to manufacture by conventional methods. In order to increase the fiber content and reduce porosity in polymer composites, it might be worthwhile to look into printing composite structures using thermoset polyimides with higher temperature performance and lower viscosity by selective laser sintering (SLS) for future works.

5. ACKNOWLEDGEMENTS

The authors would like to thank Drs. Mike Dudley and Koushik Datta from NASA Aeronautics Research Institute for their continuous support and encouragements. In addition, we would like to thank Michael Vinup, Natalie Wali and Don Weir of Honeywell Aerospace for providing component CAD files, and the following collaborators for their contribution in terms of material characterization and mechanical testing efforts for this report: Pete Bonacuse, GRC-LMA, Joy Buehler, LMA-VPL, Chris Burke, LM-SLI, Chris Kantzos, GRC, LERCIP intern, Rich Martin, LMA-CSU, Linda McCorkle and Daniel Scheiman, LMN-OAI, D. Jordan McCrone, LMA-VPL, Bob Pelaez, GRC-FTH, Larry Smith, FTC-Jacobs, Tim Ubienski, FTH-SLI, Nathan Wilmoth, LMA-VPL, Chao Lao, Morgan Rhein and Jeremy Mehl/2014 NASA Academy Students and rp+m staffs.
