The impact of standard semiconductor fabrication processes on polycrystalline Nb thin film surfaces

Ari D. Brown, Emily M. Barrentine, Samuel H. Moseley, Omid Noroozian, and Thomas Stevenson

Abstract—Polycrystalline Nb thin films are extensively used for microwave kinetic inductance detectors (MKIDs) and superconducting transmission line applications. The microwave and mm-wave loss in these films is impacted, in part, by the presence of surface nitrides and oxides. In this study, glancing incidence x-ray diffraction was used to identify the presence of niobium nitride and niobium monoxide surface layers on Nb thin films which had been exposed to chemicals used in standard photolithographic processing. A method of mitigating the presence of ordered niobium monoxide surface layers is presented. Furthermore, we discuss the possibility of using glancing incidence x-ray diffraction as a non-destructive diagnostic tool for evaluating the quality of Nb thin films used in MKIDs and transmission lines. For a given fabrication process, we have both the x-ray diffraction data of the surface chemistry and a measure of the mm-wave and microwave loss, the latter being made in superconducting resonators.

Index Terms—Superconducting integrated thin film circuits, superconducting photodetectors, dielectric films, dielectric losses.

I. INTRODUCTION

A new class of superconducting spectrometers-on-a-chip operating in the sub-mm to mm spectral bands, which includes Micro-Spec [1], SuperSpec [2], and DESHIMA [3], are envisioned to become integral space-borne or balloon-borne instruments due to their compact size. The salient components that all three of these instruments have in common are superconducting microwave kinetic inductance detectors (MKIDs), superconducting transmission lines, and superconducting slot antennas. The MKIDs are read out at microwave frequency, and the incoming sub-mm and mm radiation are coupled to the superconducting transmission lines via the antenna. Consequently, microwave and mm-wave loss in these components may have a deleterious impact on the optical efficiency, spectral bandwidth, and resolving power of these instruments.

One source of electromagnetic loss in superconducting components is the dielectric loss of metal oxides and nitrides, which is correlated with two-level system (TLS) fluctuations [4]. Microwave [5] and millimeter [6] power is resonantly coupled to an ensemble of TLS, which contributes to loss in the material.

Various techniques may be used to identify the presence of surface nitrides and oxides, which include X-ray photoelectron spectroscopy [7], Rutherford backscattering spectroscopy [8], Auger electron spectroscopy, and glancing incidence x-ray diffraction [9]. Glancing or grazing incidence x-ray diffraction is a surface-sensitive technique, in which the sample is probed following the Bragg condition and Snell’s law for total external reflection [10]. The latter case is applicable, because the refractive index of a dense material is less than unity at x-ray wavelength. Consequently, at angles of incidence below a critical angle \( \theta_c \), the x-rays evanescently couple with the material. Thus, the x-ray penetration depth inside a material can vary over many orders of magnitude within a small angular range [11].

Here we use glancing incidence x-ray diffraction as a means to identify niobium oxides and nitride on the surface of niobium thin films that comprise the superconducting transmission lines and antenna on Micro-Spec. We find that the presence of niobium monoxide is correlated with a high frequency cut-off in the sub-mm transmission lines of the spectrometer. Furthermore, we evaluate our fabrication process and find that the exposure of positive photoresist to niobium surfaces with a native oxide promotes the formation of an ordered niobium monoxide layer. In addition, a simple means to prevent the formation of this ordered metal oxide layer is presented.

II. DETECTION OF SURFACE OXIDES ON Nb THIN FILM SURFACES

The motivation of searching for surface oxides on Nb thin films arises from an anomalous high frequency cut-off of a Micro-Spec prototype [1]. Micro-Spec operates by coupling radiation to a slot antenna which is then propagated down a microstrip transmission line. The radiation is then split into \( N \) equal components which are appropriately phased with microstrip transmission lines of different length. This “delay line network” is analogous to a diffraction grating, and radiation exiting the network is allowed to propagate in a two-dimensional multimode region. Convergent circular wavefronts from the different wavelengths focus the radiation at different locations at the opposite end of the multimode region and provide the desired dispersion. Finally, the radiation is fed to and detected by the MKIDs.

Figure 1 shows the spectral response of the reference resonators on two Micro-Spec devices, which were fabricated on two separate runs. The reference resonators bypass the spectrometer and are coupled to the slot antenna by 37 mm of...
Nb microstrip line. The spectral response of the “new generation” device is characterized by a sharp high frequency cutoff at 450 GHz. In contrast, transmission down the microstrip line is attenuated much more slowly in the “old generation” device, and radiation ceases to propagate down the transmission line at a much higher frequency. It was expected that the high frequency cutoff would be approximated by the gap frequency of Nb~3.5-4 kBTc/h ~ 630-750 GHz [12], because the microstrip transmission line is comprised of a Nb ground plane and Nb top layer separated by a 470 nm single crystal Si dielectric. Thus, it was suspected that one or both of the Nb layers in the new generation device either had bulk or surface contaminants, which might decrease $T_c$ or increase the loss tangent, respectively, or high tensile stress, which has been shown to be responsible for an increase in the loss tangent of Nb thin films [13].

![Fig. 1. Spectral response of the reference resonators on two Micro-Spec devices. The reference resonators on both devices were coupled to a slot antenna via a Nb microstrip transmission line which was comprised of a top Nb layer and Nb ground plane separated by a single crystal Si dielectric. The ground plane layers were deposited during the same deposition run. Consequently, it was believed that the top Nb layer was responsible for the observed high-frequency cutoff.](image)

Fabrication of the Micro-Spec devices followed a process described in [14]. The Nb ground plane was DC magnetron sputter deposited (at 350 W and with 3.18 mT of Ar) and lifted off on a silicon-on-insulator (SOI) wafer, after which the Si device layer was bonded to a silicon handle wafer with Benzocyclobutene (BCB). The SOI handle wafer was then removed via mechanical lapping and deep reactive ion etching, and the buried oxide was etched with dilute HF. Aluminum or Mo$_2$N/Mo/Mo$_2$N MKIDs were deposited, patterned, and etched on the opposite side of the Si device layer (of the Nb ground plane) on the new and old generation devices, respectively, and the top Nb layers were lifted off. Palladium-gold resistive layers were lifted off and ground plane access regions were exposed with reactive ion etching of the Si device layer.

The last fabrication steps, which consisted of depositing an impedance matched coating on the wafer back side (for stray light mitigation) and dicing the individual Micro-Spec dice, were the ones in which the processing for the new and old generation devices was substantially different. Fabrication of the old generation devices proceeded with: Coating of the top metal layers with a passivating polymer (Gen-Arc 365), wax bonding the wafer to a Pyrex wafer, lifting off a Bi impedance matched coating, dicing the parts, releasing them in acetone, and ashing away the Gen-Arc. In contrast, the new generation devices were completed by coating the top metal layers with positive photoresist, depositing, patterning, and etching a Ti impedance matched coating, and dicing them. Thus, we hypothesized that because the top Nb layers were subjected to different processing steps, either their surface chemistries or their film stress were different.

The initial means to study whether or not there were surface impurities on the top Nb layer surface was performed with nulling ellipsometry measurements of the multimode region. The multimode region was probed because it is comprised of the same Nb top layer, Si dielectric, and Nb ground plane as the Nb microstrip lines and it is much larger than the region illuminated by the ellipsometer. This latter point allowed one to probe a region on the Micro-Spec surface that was homogeneous in the plane of the sample.

The first two rows in Table 1 describe the layer stack on top of the Nb surface of the completed MicroSpec dice. For all the devices, the range of Nb$_2$O$_5$ thickness values is similar to a value derived by d’Acapito et al., [15], who used extended x-ray absorption fine structure spectra to measure the native oxide thickness of a Nb thin film which had been exposed to atmosphere for several weeks. The presence of an additional surface layer was also predicted. Unfortunately, we had no insight into the identity of this layer, because a B-Spline model used to fit the ellipsometric data yielded dielectric constants whose values were unphysical. By performing various etching tests on different new generation Micro-Spec dice, it was inferred that the additional layer was positioned between the Nb and the Nb$_2$O$_5$.

Extracted values of surface layer thickness on top of the Nb multimode region on various Micro-Spec parts. The ellipsometric model predicted the presence of two distinct layers, which included Nb$_2$O$_5$ and an additional layer with unphysical dielectric constants. This anomalous layer was the last to be
removed upon exposure to various etchants. Consequently, it was believed that this layer was sandwiched between Nb$_2$O$_5$ and Nb.

Measurements of the Nb film stress were conducted via two methods. One method involved obtaining the global stress of the film by comparing the curvature of a witness wafer before and after deposition of the Nb with an FSM film stress measurement machine. The film stress measured with this technique ranged between -150 and +50 MPa.

The second method involved inferring the stress from glancing incidence x-ray diffraction data. Copper K$_\alpha$ x-rays were directed at a glancing angle which ranged between 0.1 and 8.0 degrees of the sample with an Equinox-100 (Inel) x-ray diffractometer in an asymmetric geometry. This angular range corresponded to an x-ray penetration depth ranging between 3.6 and 1105.4 nm in Nb. The Nb was found to be polycrystalline, with prominent (110), (200), and (211) diffraction peaks. Figure 2 shows that the lattice strain, $\varepsilon_{hkl}=(d_{hkl}-d_0)/d_0$, where $d_0$ is the bulk lattice parameter, of the Nb thin films can be described in terms of three regimes. Near the Nb/atmospheric interface, the Nb grains are highly strained, which suggests that a native oxide is responsible for the lattice deformation. For penetration depth slightly larger than the top Nb thickness (~270 nm), the (200)-oriented crystallites have a negative strain, which may suggest that the Si substrate is impacting the growth of the film. Finally for penetration depth > 500 nm, in which the ground plane is most likely being probed, the lattice strain is almost identical to that of the bulk value. The sin $^2$Ψ (where Ψ=θ−ω) method was used to estimate the stress [16] for a penetration depth much larger than the top Nb thickness (~270 nm), which yields stress values of ~190(110) and 670 (500) MPa in the [200] and [211] directions; in the [110] direction, the stress was found to be ~1.7 (1.0) GPa for penetration depth of 550-760 nm and -1.5 (-1.6) GPa for larger penetration depth for the new (old) generation device. Due the fact that there were two different Nb layers present it was difficult to ascertain which layer was stressed.

![Fig. 2. The lattice constant of Nb in the multimode region on a new generation Micro-Spec device.](image)

Fig. 3. Glancing incidence X-ray diffraction scans on the multimode region of a new and old generation Micro-Spec device. The solid lines, dashed lines, and dotted line indicate the position of the Nb, NbO, and NbN diffraction peaks, respectively. Whereas the labels for the Nb peaks are located to the right of the lines, the labels are located to the left of the lines for NbO and NbN. Note that in order to distinguish these peaks from the background, extremely long (10s of hours) integration times were used.

III. SOURCE AND MITIGATION OF NIOBIUM MONOXIDE AND NIOBIUM NITRIDE ON NB THIN FILM SURFACES

In order to further understand the processes responsible for the observation of pronounced NbO x-ray diffraction peaks on the new-generation Micro-spec devices, we performed a simple experiment on Nb-coated Si(001) wafers. As described above, one of the major differences between the old and new
generation Micro-spec devices is that whereas the Nb surface of the old generation devices were exposed to Gen-Arc 365 during backside processing, the Nb on the new generation devices was exposed to positive photoresist (S-1827, Shipley). Thus, it was hypothesized that a Nb surface exposed to positive photoresist would have an ordered NbO surface layer, which would be seen in glancing incidence x-ray diffraction data.

The experiment consisted of spinning photoresist on a Nb-coated wafer, with, presumably, a native oxide layer on its surface, with the same spin speed and time used for coating the new generation Micro-Spec wafers (3000 rpm, 30 sec). The resist was then soft baked on a vacuum hotplate for 1 min at 110 C in order to mimic the process used to prepare the wafer for dicing. Furthermore, the resist was hotplate baked for (1) an additional two minutes at 110 C in order to mimic the process used to protect the front side of the wafer in preparation for deposition of the backside Ti, and (2) an additional 30 minutes at 90 C in an oven in order to mimic the process used to pattern the Ti. Subsequently, the photoresist was stripped with organic solvents.

Figure 4 confirms our hypothesis, because well-defined diffraction peaks corresponding to NbO are clearly observed for the sample that had been coated with photoresist. In contrast, the diffraction pattern of a “control” sample, which consisted of a bare Nb film, exposed to atmosphere for two weeks, did not. Furthermore, when hexamethyldisilazane (HMDS) was used to passivate the Nb surface prior to coating it with photoresist, the clearly defined NbO diffraction peaks were not observed.

At present, we are uncertain about the mechanism responsible for the formation of an ordered NbO layer on Nb surfaces exposed to positive photoresist. Perhaps the carbonyl group in the propylene glycol methyl ether acetate (PGMEA) found in S-1827 photoresist is responsible for changing the oxidation state of the disordered layer located between Nb2O5 and Nb, and the HMDS serves as a barrier against such a reaction.

We were also interested in the impact of an ordered NbO layer on the microwave properties of Nb thin films. The resonators were fabricated by direct-sputter depositing Nb on a rotating Si(001) wafer (p>2000 Ωcm), passivating the Nb with HMDS, and patterning it with positive photoresist. The Nb was reactive ion etched with a CF4/O2 plasma, after which the resist was cleaned with an organic base (EKC-265). Then the wafer was cleaved in half, and the wafer was prepared for dicing either by spinning on S-1811 photoresist and baking it using the protocol to generate the formation of an ordered NbO phase described earlier in this Section or by passivating the surface with HMDS and coating it with photoresist. We found that the range of quality factors of the resonators at 165mK driven by -60 dBm of ~3.5 GHz radiation was 3-8x10^5 and 2-3x10^5 for the unpassivated and passivated Nb, respectively. Furthermore, the latter devices had resonant frequency that was 10-40 MHz higher.

IV. CONCLUSIONS

The presence of an ordered NbO phase was detected on Nb thin film surfaces exposed to positive photoresist using glancing incidence x-ray diffraction. The formation of this phase could be prevented by passivating the Nb surface with HMDS, and its presence might have impacted the millimeter and microwave properties of Nb.
