Abstract: OH and CH₂O were imaged in a premixed, cavity-anchored, ethylene-air turbulent flame using a high-resolution planar laser-induced fluorescence (PLIF) system. The electrically-heated, continuous flow facility (UVa Supersonic Combustion Facility, Configuration E) consisted of a Mach 2 nozzle, an isolator containing flush-wall fuel injectors, a combustor with a cavity flameholder and optical access, and an extender. Standard test conditions comprised total temperature 1200 K and total pressure 300 kPa, local equivalence ratios near 0.4, and local Mach number near 0.6 in the combustor. OH and CH₂O were excited in separate experiments with planar laser sheets at 283.55 nm and 352.48 nm, respectively. A laser sheet of approximate thickness 25 μm illuminated a streamwise plane that bisected the cavity. This plane was imaged between the backward-facing step and 120 mm downstream of the step. The intensified camera system imaged OH with magnification 1.91, a square 6.67 mm field of view, and in-plane resolution 39 μm. The smallest observed OH structures were approximately 110 μm wide. CH₂O PLIF was captured with poorer resolution; structures as small as 200 μm were observed. Composite fluorescence images were computed for the observed area.

Keywords: scramjet, cavity flameholder, PLIF, high-resolution visualization

1. Introduction

High-resolution OH and CH₂O PLIF imaging was performed at the University of Virginia Supersonic Combustion Facility (UVaSCF) on a premixed ethylene-air flame that was anchored and stabilized by a cavity flameholder. The UVaSCF is a continuous-flow, electrically-heated, clean-air ground test facility with optical access that produces an enthalpy simulating a Mach $M = 5$ scramjet flight. This work corresponds to UVaSCF “modified Configuration E” [1]: a $M = 2$ nozzle followed by an isolator with fuel injectors, a combustor test section, and an outlet. Tests were performed with total temperature 1200 K, total pressure 300 kPa, local equivalence ratios near 0.4, and $M = 0.6$ at the combustor.

Nonintrusive optical diagnostic techniques such as planar laser-induced fluorescence (PLIF) are often used to characterize turbulent flame structures [2]. PLIF is a technique in which a cylindrical lens expands a circular laser beam in a given direction and then a spherical lens collimates the beam in the given direction and focuses it in the orthogonal direction, creating a
thin sheet of laser light. The wavelength of this sheet is tuned to match an absorption band of a chemical species of interest, usually an intermediate product of combustion. The species emits broadband fluorescence, which is captured by an intensified camera. This provides an instantaneous, planar map of qualitative or quantitative concentration measurements. PLIF images can be compared to computational species concentration results in order to refine computational and theoretical models.

Previous studies have imaged OH [3] and CH$_2$O [4] at UVaSCF; the current work presents data at a higher spatial resolution, resolving smaller flame structures. The resolution of PLIF images depends on both the resolution of the imaging and camera system and on the laser sheet thickness. Turbulent flows are highly three-dimensional, and PLIF signal is integrated over the sheet thickness. Obtaining a sharp image of small structures is therefore dependent on creating a thin laser sheet.

The smallest possible perturbations in a turbulent flow are on the order of the Kolmogorov length scale $\eta$. This is the length over which turbulent kinetic energy can be dissipated by viscosity. Previous particle image velocimetry experiments and computational investigations of the current flowpath [5] have yielded estimates for the integral length scale $L = 5$ mm, root-mean square velocity $u = 50$ m/s, and kinematic viscosity $v = 4$ to 5 m$^2$/s. The expression [6] $\eta = (v/u)^{3/4}L^{1/4}$ yields $\eta = 7$ to 8 $\mu$m. The smallest flame structures are expected to be around ten times larger than the Kolmogorov length scale [7]. Therefore, a PLIF system that has both planar resolution and laser sheet thickness smaller than 70 $\mu$m should be able to observe the smallest flame structures in the flow.

2. Set-up

A long-duration visible light image of the cavity-stabilized flame is shown in Figure 1; the coordinate system shown originates in the plane of the backward-facing step at the downstream projection of the center of the nozzle exit. One wall had a copper insert with a cavity of step height $H = 9$ mm. Two side walls of the test section had quartz windows for camera access. The wall opposite the cavity had a quartz window for laser sheet insertion.

The PLIF beam path is described in Figure 2. A Q-switched Spectra-Physics Nd:YAG laser created a 1064 nm beam at 20 Hz. After frequency-doubling, the 532 nm beam pumped a Sirah Cobra-Stretch dye laser. For OH PLIF, the frequency-doubled dye laser output was tuned to
283.5525 nm, to excite the temperature-independent [3] [8] Q(8) transition of OH. The width of the laser sheet was decreased by a spatial filter (which was created using the entrance slit for a spectrometer) in which the gap between the blunt sides of two steel blades was set by an adjustable knob. By narrowing the gap around the beam focus, the broad wings of the laser sheet were removed. The thickness of the OH PLIF laser sheet waist was measured using a 2448 x 2048 pixel, 16-bit CCD Point Grey beam-profiling camera (with the ultraviolet filter removed). The laser sheet had full width at half-maximum of approximately 25 μm. Figure 3 shows profiles of laser sheet intensity at different spatial filter settings. The 125 μm setting was used for this data; smaller values caused slow ablation of the spatial filter.

![Figure 3. Effect of spatial filter setting on laser sheet intensity profile. Settings are not absolute aperture widths; they are offset by an unknown constant value.](image)

PLIF images were taken using a PI-Max 4 intensified CCD camera with a square 13.1 mm sensor. OH PLIF images were taken with a 100 mm focal length, f/2.8 Cerco camera lens, with 203.2 mm of extension tubes and a Semrock FF02-320/40-30-D filter (bandpass from 310 to 340 nm) to block laser reflection and other interferences. The camera setup for OH PLIF was characterized using a USAF-1951 resolution target. The system had magnification 1.9, corresponding to a field-of-view 6.86 x 6.86 mm across 512 x 512 pixels (or 13.4 μm/pixel) after 2 x 2 binning. The in-plane resolution was about 39 μm, based on a contrast transfer function of 50%. Three different motorized translation stages moved the sheet optics and the camera together to image different areas of the flow. Relay mirrors were used such that the laser sheet focus did not change during translation. A fourth motorized translation stage was used to move the camera towards or away from the laser sheet, adjusting the focus.

For CH₂O PLIF, laser output was tuned to 352.484 nm, using the A(2)A(4) − A(1)A(4) transition system commonly used to excite CH₂O [9]. Compared to the OH PLIF experiment, changes were made to the optical setup to promote a higher signal-to-noise ratio. The cylindrical lens focal length (Element 5 in Figure 2) was increased to 200 mm, increasing laser sheet intensity by a factor of four. The camera was fitted with a visible light f/2 lens. The system had magnification 2.14, corresponding to a field-of-view 6.11 x 6.11 mm across 256 x 256 pixels (or 23.9 μm/pixel) after 4 x 4 binning. The camera used a GG-395 Schott filter to block laser reflection.

3. Methods and data processing

To investigate a large area, images were taken while the translation system’s x-axis motor was in motion. Camera focus was periodically adjusted. Background image sets were acquired with the laser blocked. Mean background images have been subtracted from all presented results.
For OH PLIF, the camera travelled along the $x$-axis at 0.25 mm/s while acquiring images at 10 Hz, resulting in 40 images for every millimeter. Six $x$-direction sweeps were acquired from $x/H = 0$ to 14.10, and from $y/H = -1.75$ to 1.61.

CH$_2$O PLIF images were captured at 20 Hz while the camera travelled at 0.5 mm/s. Five $x$-direction sweeps were captured from $x/H = 0$ to 14.01, and from $y/H = -1.75$ to 0.99. Imaging was attempted closer to the cavity wall, but the ablation of the wall by the laser created bright interference that obscured flame structure in many images.

4. Results and discussion

Figure 4. Selected OH PLIF images. False color. Downstream of cavity. Image center coordinates: $x/H =$ (a) 5.00, (b) 5.05, (c) 5.66, $y/H = 0.51$.

Figure 6. OH PLIF intermittency boundaries. Based on threshold signal intensity 6,000 counts.

For OH PLIF, Figure 4 shows selected single shot images, while Figure 5 shows a compilation of single shots across the test section. In these images, OH signal marks the location of combustion products in the flow. The edge of the signal is the interface between reactants and products. This
marks the general location of the flame front [10]. The images show evidence of flamelets [11], where reactants and products are separated by wrinkled flames on the order of 100 μm wide.

Intermittency was calculated across the test section. For a given pixel location, intermittency [3] is defined as the fraction of images in which significant OH signal is detected. Figure 6 shows flame boundaries with 10% and 90% intermittency. This gives a visualization of the region in which the flame front oscillates.

The images were analyzed for the smallest flame structures in the flow. Figure 7 shows an OH PLIF intensity profile (at the yellow line) across a small flame structure (in the lower right quadrant of the first image in Figure 4.) It has a full width at half-maximum of approximately 110 μm, and is representative of the smallest structures observed. This is slightly larger than the predicted size for the smallest flame structures (70 – 80 μm.) No structures near the predicted resolution of the system (39 μm) were observed. This suggests that this OH PLIF system is capable of resolving all flame structure length scales for this turbulent compressible flowfield.

For CH$_2$O PLIF, selected single shots are presented in Figure 8. CH$_2$O signal marks the preheat zone of the flame [10], which in some locations is significantly wider than the flame thickness. The smallest observed CH$_2$O were larger than the smallest OH features, approximately 200 μm wide. This may be due to significantly decreased signal intensity as well as decreased spatial resolution caused by increased pixel binning. CH$_2$O PLIF images suffered from a much smaller signal-to-noise ratio than OH PLIF. CH$_2$O PLIF images were also frequently marred by bright interference created by the laser sheet ablating the copper wall.

5. Conclusions

This work has demonstrated an OH PLIF system that can resolve premixed turbulent flame structures in a high-speed compressible reacting flow as small as 25 x 40 x 40 μm$^3$. However, the
observed CH$_2$O PLIF signal was much weaker than the OH PLIF signal, resulting in decreased resolution. Work is ongoing to improve these issues with high-resolution CH$_2$O PLIF.
