Introduction: Metallic cores contain light alloying elements that can be a combination of S, C, Si, and O, all of which have important chemical and physical influences. For Earth, Si may be the most abundant light element in the core [1]. Si dissolved into Fe liquids can have a large effect on the magnitude of the activity coefficient of siderophile elements (SE), and thus the partitioning behavior of those elements between core and mantle [2,3,4]. The effect of Si on the highly siderophile elements is only beginning to be studied and the effects on Au, Pd and Pt are significant [5]. Here we report new experiments designed to quantify the effect of Si on the partitioning of Re between metal and silicate melt. A solid understanding of Re partitioning is required for a complete understanding of the Re-Os isotopic systems. The results will be applied to understanding the HSEs and Os isotopic data for planetary mantles, and especially Earth.

Experimental: Experiments were carried out using a piston cylinder apparatus and run conditions of 1 GPa and 1600 ºC (Fig. 1). The starting materials comprised basaltic silicate (70% by mass) mixed with metallic Fe + 5% Re. Silicon metal was also added to the metallic mixture at 2, 4, 6, and 10 %, to alloy with the Fe liquid and create a variable amount of Si alloyed with Fe. The MgO capsule reacts with the silicate melt to form more MgO-rich liquids that have 22-26 wt% MgO.

Analytical: Experimental metals and silicates were analyzed using a combination of electron microprobe analysis (EMPA) at NASA-JSC, and laser ablation ICP-MS at Florida State University. EMPA analysis (using JEOL 8530 FEG microprobe) was used for major and minor elements and utilized a variety of mineral and glass standards with 15 kV and 20 nA conditions. Rhenium and other trace siderophile elements (typically those <100 ppm) were measured with LA-ICP-MS using glass and metal standards and either spot or line analyses depending on the size of the metal or silicate regions of interest.

Results: Measured Re and other siderophile elements were used to calculate metal (met) - silicate (sil) exchange $K_d$ according to this equation:

$$\ln K_d - \ln \gamma_{Re}^{\text{metal}} = \varepsilon_{Re}^{\text{Si}} \ln (1-X_{Si}) + \text{const} - \ln \gamma_{Re}^{\text{silicate}}$$

Expanding equation (1) and following a similar approach to [5], the exchange coefficient $K_d$ can be represented as:

$$\ln K_d - \ln \gamma_{Re}^{\text{metal}} = \varepsilon_{Re}^{\text{Si}} \ln (1-X_{Si}) + \text{const} - \ln \gamma_{Re}^{\text{silicate}}$$

Here $\gamma_{Re}^{\text{metal}}$ is the activity of Re in Fe metal at infinite dilution, $\gamma_{Re}^{\text{silicate}}$ is the activity coefficient of Fe in metallic liquid, and $\varepsilon_{Re}^{\text{Si}}$ is an interaction parameter (e.g., [5,6,7]) that can be used to isolate the effect of a solute such as Si (in Fe metallic liquid) on the activity of a trace element such as Re. The slope of ln$K_d$ versus $\ln (1-X_{Si})$ gives $\varepsilon_{Re}^{\text{Si}}$ directly for each element.

![Figure 1: Reflected light photo of metal-silicate experiment Re-4B at 1600 ºC and 1 GPa. Metallic sphere (bright white) contains Fe-Si-Re, and the surrounding silicate melt contains ~25 wt% MgO. Capsule material is MgO; width of field is ~ 3 mm.](https://ntrs.nasa.gov/search.jsp?R=20180002592 2018-11-27T05:24:46+00:00Z)

![Figure 2: ln$K_d$(Fe-Re) – ln$\gamma_{Fe}$ versus ln (1-X$_{Si}$) from 5 experiments across a wide range of Si contents in metallic Fe.](https://ntrs.nasa.gov/search.jsp?R=20180002592 2018-11-27T05:24:46+00:00Z)

We have previously determined $\varepsilon_{Re}^{\text{Si}}$ for a large number of siderophile elements (M) [5,6,7], and here present the results for Re which has a high value of $\varepsilon_{Re}^{\text{Si}} = 45$ at 1 GPa and 1600 ºC (Fig. 2). This high value is comparable to what we’ve found for P, Bi, Sn,
As, and Sb [5,6,7], and much higher than some of the moderately siderophile elements such as Ni, Co, and W [2,5].

**Application:** We apply this model to Earth (with a likely Si-rich core), and examine the variation of activity coefficient for Re in core-forming metal during accretion. Two accretion models are considered for Earth—relatively constant fO2 and variable fO2—and include the evolving S, C, Si content of the core as accretion proceeds. Models with variable fO2 have large compositional changes in the metallic liquid which also cause orders of magnitude change in the activity coefficient of the trace SE (Fig. 4). These large activity coefficients under conditions of a deep magma ocean will lower D(Re) metal/silicate by several orders of magnitude, which would result in higher Re concentrations in the early mantle.

When these activity variations are combined with pressure and temperature effects, the mantle abundances of these elements can be calculated for a deep magma ocean. For example, the combination of the temperature and pressure effects measured by [14] and the Si effects measured here may lead to mantle Re contents much closer to those measured in the primitive upper mantle (PUM). We will consider models of variable depth magma ocean to test whether: 1) Re concentration of the PUM can be explained by metallic-silicate equilibrium, or 2) Re also becomes “overabundant” in the mantle requiring a removal mechanism such as segregation of a late sulfide matte [8], and 3) an additional source of Re is required, such as from a late veneer [15].

The model derived here can also be used to evaluate models for core formation in bodies of variable size and cores of variable compositions such as the reduced aubrites and acapulcoite-lodranite parent bodies, or applied to Mars (S-rich core), Moon (S-, C-, and Si-poor core), and Vesta.
