A 400-solar-mass black hole in the galaxy M82

Dheeraj R. Pasham1,2, Tod E. Strohmayer2 & Richard F. Mushotzky1

M82 X-1, the brightest X-ray source in the galaxy M82, has been thought to be an intermediate-mass black hole (100 to 10,000 solar masses) because of its extremely high luminosity and variability characteristics1–4, although some models suggest that its mass may be only about 20 solar masses3,7. The previous mass estimates were based on scaling relations that use low-frequency characteristic timescales which have large intrinsic uncertainties8,9. For stellar-mass black holes, we know that the high-frequency quasi-periodic oscillations (100–450 hertz) in the X-ray emission that occur in a 3:2 frequency ratio are stable and scale in frequency inversely with black hole mass with a reasonably small dispersion10–13. The discovery of such stable oscillations thus potentially offers an alternative and less ambiguous means of mass determination for intermediate-mass black holes, but has hitherto not been realized. Here we report stable, twin-peak (3:2 frequency ratio) X-ray quasi-periodic oscillations from M82 X-1 at frequencies of 3.32 ± 0.06 hertz and 5.07 ± 0.06 hertz. Assuming that we can extrapolate the inverse-mass scaling that holds for stellar-mass black holes, we estimate the black hole mass of M82 X-1 to be 428 ± 105 solar masses. In addition, we can estimate the mass using the relativistic precession model, from which we get a value of 415 ± 63 solar masses.

Oscillations arising from general relativistic effects should scale inversely with black hole mass if they arise from orbital motion near the innermost stable circular orbit in the accretion disk16,17, and there is observational support that they do for stellar-mass black holes10 (3–50 solar masses (M⊙)). Previous estimates of the mass of M82 X-1, of a few

Figure 1 | Power density spectra of M82. a, Six-year average X-ray (3–13 keV) power density spectrum of M82 using 7,362 individual 128 s light curves. The frequency resolution is 0.125 Hz. The two strongest features in the power spectrum occur at 3.32 ± 0.06 and 5.07 ± 0.06 Hz, consistent with a 3:2 frequency ratio. b, Averaged power density spectrum of all (363) 1,024 s segments. The frequency resolution is 0.0625 Hz. The strongest feature is at 5 Hz. c, For a direct comparison with stellar-mass black holes, we show the broadband power density spectrum of M82 (using ~100 ks of XMM-Newton/EPIC data; ID: 0206080101) showing the low-frequency quasi-periodic oscillation at 120 mHz in addition to the high-frequency quasi-periodic oscillation pair in a and b. Power spectra are Leahy-normalized to a value of 2.
hundred solar masses, combined with the type-C identification\textsuperscript{7,8,9} of its millihertz X-ray quasi-periodic oscillations, suggest that 3:2-ratio, twin-peak, high-frequency oscillations analogous to those seen in stellar-mass black holes, if present, should be detectable in the frequency range of a few hertz\textsuperscript{16}. We accordingly searched NASA’s Rossi X-ray Timing Explorer proportional counter array (PCA) archival data to look for 3:2 ratio oscillation pairs in the frequency range of 1–16 Hz, which corresponds to a black hole mass range of 50M\textsubscript{☉}–2,000M\textsubscript{☉}.

We detected two power spectral peaks at 3.32 ± 0.06 Hz (with a coherence, the ratio of frequency to width, of Q = v/Δv > 27) and 5.07 ± 0.06 Hz (Q > 40), consistent with a 3:2 frequency ratio (Fig. 1a, b). The combined statistical significance of the detection is greater than 4.7σ (Methods).

The PCA’s field of view (1° × 1°) of M82 includes a number of accreting X-ray sources in addition to M82 X-1\textsuperscript{11}. The remarkable stability of the two quasi-periodic oscillations on timescales of a few years (Supplementary Videos 1 and 2), their 3:2 frequency ratio and their high oscillation luminosities strongly suggest they are not low-frequency quasi-periodic oscillations from a contaminating stellar-mass black hole (Methods). Also, a pulsar origin is very unlikely for several reasons. First, a pulsar signal would be much more coherent than that of the observed quasi-periodic oscillations, which have a finite width. Second, judging from the observed high quasi-periodic oscillation luminosities, it is extremely implausible that they originate from a pulsar (Methods). Finally, it would be highly unlikely to have two pulsars in the same field of view with spins in the 3:2 ratio. Also, on the basis of the average power spectrum of the background sky and a sample of accreting supermassive black holes monitored by the PCA in the same epoch as M82, we rule out an instrumental origin for these oscillations (Extended Data Figs 2–4).

This leaves M82 X-1, which is persistently the brightest source in the field of view, as the most likely source associated with the 3:2 quasi-periodic oscillation pair.

We estimated M82 X-1’s black hole mass, assuming first the inverse-mass scaling of stellar-mass black holes and then the relativistic precession model\textsuperscript{16,20}, to be (428 ± 105)M\textsubscript{☉} in the first case and (415 ± 63)M\textsubscript{☉} in the second (Fig. 2). Combining the average 2–10 keV X-ray luminosity\textsuperscript{21,22} of the source, of 5 × 10\textsuperscript{40} erg s\textsuperscript{-1}, with the measured mass suggests that the source is accreting close to the Eddington limit with an accretion efficiency of 0.8 ± 0.2.

The previous mass measurements of M82 X-1 have large uncertainties owing to both systematic and measurement errors. For example, modelling of its X-ray energy spectra during the thermal-dominant state using a fully relativistic, ‘multicoloured’ disk model suggests that it hosts an intermediate-mass black hole that has a mass anywhere in the range of 200M\textsubscript{☉}–800M\textsubscript{☉} and is accreting near the Eddington limit\textsuperscript{3}. In addition to the large mass uncertainty associated with the modelling, the same study also found that the energy spectra can be equally well fit with a stellar-mass black hole accreting at a rate ∼160 higher than the Eddington limit\textsuperscript{3}. Also, the X-rays from this source is known to modulate with a periodicity of 62 days, which has been argued to be the orbital period of an intermediate-mass black hole\textsuperscript{23}—formed in the nearby star cluster MCG-11 by stellar runaway collisions\textsuperscript{23,24}—accreting mate via Roche lobe overflow from a 22M\textsubscript{☉}–25M\textsubscript{☉} companion star\textsuperscript{24}. Detailed stellar binary evolution simulations suggest that the long periodicity is best explained by an intermediate-mass black hole with mass in the range of 200M\textsubscript{☉}–5,000M\textsubscript{☉} (refs 5, 24). However, a recent study finds that this periodicity may instead be due to a precessing accretion disk, in which case a stellar-mass black hole will suffice to explain the apparent long periodicity\textsuperscript{7}.

One of the main lines of argument for an intermediate-mass black hole in M82 X-1 follows from the assumption that its millihertz quasi-periodic oscillations are analogous to the type-C oscillations of stellar-mass black holes and to scale the inverse-mass relationship of the frequency of these millihertz oscillations (frequency range of 37–210 mHz (refs 9, 25; Fig. 1c) to the type-C, low-frequency X-ray oscillations (frequency range of 0.2–15 Hz (refs 10, 26)). There are two uncertainties with such scaling: first, it was unclear—until now—whether these millihertz oscillations are indeed the type-C analogues of stellar-mass black holes\textsuperscript{25}, and, second, both the type-C and the millihertz oscillations are variable, resulting in a large dispersion in the measured mass of 25M\textsubscript{☉}–1,300M\textsubscript{☉} (refs 1, 2, 4, 6). The simultaneous discovery of stable, 3:2 ratio, high-frequency periodicities and low-frequency millihertz oscillations allows us to set the overall frequency scale of the X-ray power spectrum. This result not only implies that the millihertz quasi-periodic oscillations of M82 X-1 are the type-C analogues of stellar-mass black holes, but also provides an independent, and so far the most accurate, black hole mass measurement.

Finally, it should be pointed out that although the root mean squared amplitudes (3–5% of the X-ray flux) of the oscillations reported here, and their frequencies with respect to the millihertz oscillations (a few orders of magnitude higher), are similar to those observed in stellar-mass black holes\textsuperscript{26}, they appear narrower (with Q values of 27, 40 and 80) than stellar-mass black holes, which have Q values of <20 (refs 14, 27). In stellar-mass black holes, the Q factor seems to be energy dependent in some cases\textsuperscript{14}, and it is plausible that a similar effect may be operating in this case.

METHODS

Estimating the expected significance of the quasi-periodic oscillations. The detectability (statistical significance, $n_s$) of a quasi-periodic oscillation feature can be expressed as

$$n_s = \frac{1}{1 - \frac{1}{2}} \left( \frac{S}{S_B + \Delta S} \right) \sqrt{\frac{T}{\Delta T}}$$

where $r$, $S$, $B$, $T$ and $\Delta$ are the root mean squared (r.m.s.) amplitude of the quasi-periodic oscillation, the source count rate, the background count rate, the exposure time and the width of the quasi-periodic oscillation, respectively. Assuming an r.m.s. amplitude of a few percent—similar to that seen in stellar-mass black holes—and using the mean Rossi X-ray Timing Explorer (RXTE)/PCA source and background rates obtained from prior observations, we found that the wealth of publicly available archival RXTE monitoring data spread across a time span of ~6 years would suffice for a sensitive search for high-frequency quasi-periodic oscillations in M82 X-1.

Data primer. M82 was monitored (0.5–2 ks roughly once every three days) with the RXTE/PCA between 1997 February 2 and 1997 November 25 (0.8 years) and between 2004 September 2 and 2009 December 30 (5.3 years). All the PCA observations were carried out in the GoodXenon data acquisition mode. The total number of monitoring observations was 867, which were divided among six proposals (RXTE proposal IDs: P20303, P90121, P90171, P92098, P93123 and P94123). As recommended by the data analysis guide provided by the RXTE Guest Observer Facility (https://heasarc.gsfc.nasa.gov/docs/xtc/abc/screening.html), we first screened the data to include only time intervals that satisfy the following criteria: ELV $>0.0$ & OFFSET $<0.02$ & (TIME SINCE SAA $<0$ || TIME SINCE SAA $>30$) & ELECTRON2 $<0.1$. In addition to the above standard filters, we used only X-ray events within the energy range of 3–13 keV, which translates to PCA channels 7–32. This energy range is comparable to the bandpass in which high-frequency quasi-periodic oscillations have been reported from stellar-mass black holes. Moreover, beyond 13 keV the background dominates the overall count rate by a factor greater than 10. For each observation, we used all active proportional counter units, to maximize the count rate and, thus, the sensitivity to quasi-periodic oscillations.

Before we extracted the individual power spectra, we created individual light curves (using a bin size of 1 s) from all the observations. Through manual inspection we removed a small number of observations affected by flares, because these are attributed to background events, for example gamma-ray bursts, not associated with the source. Extended Data Fig. 1 shows two sample light curves and their corresponding power spectra. They represent the typical quality of the individual light curves used in extracting the average power spectra.

Estimating the statistical significances. We first divided the data into 128 s segments and extracted their light curves with a time resolution of 1/32 s. We then constructed a Leaky-normalized power density spectrum (where the Poisson noise level is 2) from each of these 128 s light curves. All the power spectra were then combined (7,362 individual power spectra) to obtain a six-year-averaged power density spectrum of M82 (Fig. 1a).

To estimate the statistical significance of any features in the 1–16 Hz range of the six-year-averaged power density spectrum obtained using the 128 s data segments, we first ensured that the local mean was equal to 2, the value expected from a purely Poisson (white noise) process. We then computed the probability, at the 99.73% (3.0 $\sigma$) confidence level, or 3.0 $\sigma$ above the local mean, of obtaining a power density spectrum containing 20 or more $\sigma$-deviations from the local mean. By this criterion, the average power density spectrum clearly shows that while the 3.3 Hz feature is stronger during the earlier stages of the monitoring program, the 3.3 Hz feature is stronger during the later observations. Longer exposures of the order of 1–2 ks were carried out during the earlier stage of the monitoring program, which explains the higher significance of the 5 Hz feature in the average power density spectrum of the 1,024 s segments (Fig. 1b).

Right mean squared amplitude of the quasi-periodic oscillations. To calculate the r.m.s. variability amplitude of these quasi-periodic oscillations, we first determined the mean net count rate (source + background) of all the light curves used to extract the average power spectra. These values were equal to 29.9 counts s$^{-1}$ and 35.2 counts s$^{-1}$ for the power spectra with 128 s and 1,024 s segments, respectively. The r.m.s. amplitudes of the 3.3 and 5 Hz quasi-periodic oscillations, not correcting for the background, were estimated to be $1.1 \pm 0.1$% and $1.0 \pm 0.1$%, respectively. Similarly, the r.m.s. amplitude of the 5 Hz feature in the power density spectrum with 1,024 s segments was estimated to be $1.1 \pm 0.1$%. We then estimated the mean background count rate from the Standard2 data using the latest PCA background model. The mean background rates during the 128 s and the 1,024 s segments were estimated to be 18.9 counts s$^{-1}$ and 24.0 counts s$^{-1}$, respectively. After accounting for the X-ray background, we find that the r.m.s. amplitudes of the 3.3 and 5 Hz features—averaged over all of the data—are $3.0 \pm 0.4$% and $2.7 \pm 0.4$%, respectively, and the amplitude of the 5 Hz feature within the 1,024 s power density spectrum was estimated to be $3.5 \pm 0.4$%.

Furthermore, the source count rates estimated above (net minus background) represent the combined contribution from all the X-ray point sources within the PCA’s 1° × 1° field of view. Thus, the quasi-periodic oscillation r.m.s. amplitudes are underestimated. A study using the high-resolution camera on board Chandra suggests that there are multiple point sources within the 1° × 1° region around M82 X-1. Tracking the long-term variability of these sources suggests that the maximum luminosity reached by any of these sources—except for source 5 (as defined by ref. 18)—is less than one-fifth of the average luminosity of M82 X-1. Source 5 is a highly variable transient ULX with a 0.5–10 keV luminosity varying between 10$^{37}$ and 10$^{38}$ erg s$^{-1}$ (see the middle-left panel of fig. 1 of ref. 33). The quasi-periodic oscillations reported here are most probably produced by M82 X-1, which has persistently been the brightest source of any in the immediate vicinity of M82 X-1 (see the following sections). Although a precise value of the r.m.s. amplitude cannot be evaluated using the present data, we estimate an absolute upper limit by calculating the r.m.s. amplitudes of the count rate contribution from M82 X-1, assuming all the remaining contaminating sources are at their brightest ever detected. This scenario is highly unlikely but will serve as an absolute upper bound on the r.m.s. amplitudes of the quasi-periodic oscillations, assuming they are from M82 X-1. Using the values reported by ref. 33, the fraction is roughly 1.8. Thus, the true r.m.s. amplitudes of the 3.3 and 5.5 Hz quasi-periodic oscillations are estimated to be in the range of 3–5%.

Also, the M82-Newton’s EPIC instruments—with an effective area of about one-fifth of RXTE’s PCA, albeit with lower background—observed M82 at multiple epochs, with a total effective exposure of ~350 ks. These observations were taken in the full-frame observation mode with a time resolution of 73.4 ms or a Nyquist frequency of 6.82 Hz. This value is close to the quasi-periodic oscillation frequencies of interest and causes some signal suppression. Nevertheless, we extracted an average 3–10 keV power density spectrum with 128 s data segments using all the observations (2,718 individual power spectra). We do not detect any statistically significant features near 3.3 and 5.5 Hz; however, we estimate quasi-periodic oscillation upper limits (3σ confidence) of 5.2 and 6.2% r.m.s. (using equations 4.4 and 4.10 of ref. 29) at 3.3 and 5.5 Hz, respectively, which are roughly twice the r.m.s. values of the quasi-periodic oscillations detected in the PCA data.

Using the 128 s data segments from RXTE, we also studied the energy dependence of the r.m.s. amplitudes of the two oscillations (Extended Data Table 1). Although the error bars are large, there seems to be a modest decrease in the r.m.s. amplitudes of these oscillations at lower X-ray energies. M82-Newton’s EPIC instruments are more sensitive in the 3–8 keV band, which is comparable to PCA channels 7–18 (the first and the fourth rows of Extended Data Table 1). Signal cannot be from a single observation. The very presence of these two features in the six-year-averaged power spectrum suggests that they are stable on this time-scale. To further rule out the possibility that these oscillations are due to a single particular observation, or a small number of them, we constructed two dynamic average power spectra, one for the 128 s segments (dynamic power density spectrum #1; Supplementary Video 1) and another for the 1,024 s segments (dynamic power density spectrum #2; Supplementary Video 2). These track the evolution of the average power density spectra as a function of the total number of individual power spectra used in constructing the average. The two dynamic power density spectra clearly suggest that the power in these two features builds up gradually as more data are averaged, as opposed to appearing suddenly, which would be expected if a single or a small number of observations were contributing all the signal power. In addition, dynamic power density spectrum #1 clearly shows that while the 5 Hz feature is stronger during the earlier stages of the monitoring program, the 3.3 Hz feature is stronger during the later observations. Longer exposures of the order of 1–2 ks were carried out during the earlier stage of the monitoring program, which explains the higher significance of the 5 Hz feature in the average power density spectrum of the 1,024 s segments (Fig. 1b).
Ruling out low-frequency quasi-periodic oscillations. Low-frequency quasi-periodic oscillations of stellar-mass black holes, such as the type-C quasi-periodic oscillations\(^2\), have typical centroid frequencies of a few hertz with r.m.s. amplitudes\(^2\) of 5–25%, but are known to vary in frequency by factors of 8–10 over timescales of days\(^3\). This would lead to very broad features in the kind of average power spectrum we have used. Moreover, among the plethora of low-frequency quasi-periodic oscillations at present known, there is no indication of them preferentially occurring with a 3:2 frequency ratio. Furthermore, the average luminosity of the quasi-periodic oscillations reported here is \(-0.03\times 10^{38}\) erg s\(^{-1}\), which is \(-0.03\times 10^{38}\) erg s\(^{-1}\). This is comparable to or more than the peak X-ray luminosities of the contaminating sources, except for source 5 (refs 33, 36). Therefore, if these features were simply low-frequency quasi-periodic oscillations produced by any of the contaminating sources—except for source 5—their X-ray flux would have to be modulated at almost 100%, which is not plausible for the typical amplitudes of low-frequency quasi-periodic oscillations.

Source 5, which is a ULX, could in principle be the origin of these 3:2 ratio quasi-periodic oscillations. However, \(-3\rightarrow5\) MHz quasi-periodic oscillations have been discovered from this source and have been identified as type-A/B quasi-periodic oscillations analogous of stellar-mass black holes\(^7\). Such a characterization for the millihertz quasi-periodic oscillations suggests that the ULX might host a black hole with a mass of \(12,000\,M_\odot\)–43,000\,M_\odot\) (ref. 37). If that were the case, the expected frequency range of high-frequency quasi-periodic oscillation analogues for a few-10,000\,M_\odot\) black hole would be a few 100s of millihertz, which is a factor of 10 lower than the quasi-periodic oscillations reported here, suggesting that the 3:3 and 5:3 Hz quasi-periodic oscillations are less likely to be the high-frequency quasi-periodic oscillation analogues of source 5.

Ruling out pulsar origin. Rotation-powered pulsars can be strongly excluded, because they simply cannot provide the required luminosity. A neutron star’s rotational energy loss rate can be expressed in terms of its moment of inertia, \(I\), spin period, \(P\), and period derivative, \(\dot{P}\), as

\[
\dot{E}_\text{rot} = \frac{2\pi I P}{P^2} \dot{P}
\]

No known pulsar has a spin-down luminosity comparable to the estimated quasi-periodic oscillation X-ray luminosity. For example, the energetic Crab pulsar has \(\dot{E} \approx 2 \times 10^{30}\) erg s\(^{-1}\), and only a fraction of a pulsar’s spin-down power typically appears as X-ray radiation. This rules out rotation-powered pulsars. Because M82 is a starburst galaxy, it probably hosts a population of accreting X-ray pulsars. Such accretion-powered pulsar systems are typically limited by the Eddington limit, of \(\approx 2 \times 10^{38}\) erg s\(^{-1}\), for a canonical neutron star. Useful comparisons can be made with the population observed with the RXTE/PCA in the Small Magellanic Cloud\(^1\). The authors of ref. 38 presented pulsar luminosities for the Small Magellanic Cloud pulsar population, and none was larger than \(\approx 3 \times 10^{38}\) erg s\(^{-1}\). Again, this is much smaller than the inferred quasi-periodic oscillations luminosities. Moreover, such pulsars are variable, and their time-averaged luminosities would be reduced further by their outburst duty cycles. At present, the only pulsar that is known to reach luminosities of \(\approx 10^{39}\) erg s\(^{-1}\) for brief periods of time is GRO J1744–28—the ‘bursting pulsar’\(^2\). This object has a 2.1 Hz spin frequency and was discovered during an outburst that spanned the first 3 months of 1996 (we note that at the time of writing the source was detected in outburst again, suggesting a duty cycle of about 18 years\(^3\)-\(^4\)). Its peak persistent luminosity (assuming a distance close to that of the Galactic centre) was \(-7 \times 10^{30}\) erg s\(^{-1}\). With a pulsed amplitude of about 10%, this would still give a pulsed luminosity much less than the inferred luminosities of the quasi-periodic oscillations. The type—II—accretion driven—bursts from this source\(^5\) could reach about \(10^{39}\) erg s\(^{-1}\); and with a 10% pulsed amplitude this could give an instantaneous luminosity close to that of the average quasi-periodic oscillation luminosities. However, the bursting intervals make up less than 1% of the total time, and this small duty cycle will thus reduce the average pulsed luminosity due to the bursts to a level substantially below that of the observed quasi-periodic oscillations. Thus, we conclude that the observed quasi-periodic oscillations cannot be associated with accreting pulsars in M82.

Ruling out instrumental origin. We also rule out the possibility that this signal is intrinsic to RXTE/PCA by extracting the average power density spectra of a sample of accreting supermassive black holes with PCA count rates comparable to M82. To be consistent, we used only monitoring data taken in the GoodXenon mode during the same epoch as M82. The long-term light curves of these sources in the same time range as M82 are shown in Extended Data Fig. 2. On the basis of the causality argument, active galactic nuclei with black hole masses greater than \(10^6\,M_\odot\) cannot have coherent oscillations at frequencies higher than \(-0.1\) Hz. The average power spectra obtained with PCA in the 3–13 keV bandpass are essentially flat and are consistent with being Poisson noise (Extended Data Fig. 3). In addition, we also extracted the average power spectrum of a blank sky field (background) monitored using the GoodXenon mode during the same epoch as M82. The corresponding average power spectrum is shown in Extended Data Fig. 4b and is again consistent with being featureless, as expected.

Relativistic precession model analysis. According to the relativistic precession model, the upper harmonic of the high-frequency quasi-periodic oscillation is associated with the Keplerian frequency at some inner radius, and the lower harmonic of the high-frequency quasi-periodic oscillation and the type-C quasi-periodic oscillation is associated with the periastron and nodal precession frequencies, respectively, at the same radius. Recently, this model was applied to GRO J1655–40\(^5\), which exhibits both low-frequency and high-frequency quasi-periodic oscillations and has a very accurate mass measurement of \((5.4 \pm 0.3)\,M_\odot\) (ref. 28). They find that the black hole mass evaluated from the relativistic precession model analysis agrees nicely with its dynamical mass estimate. Given this promise of the relativistic precession model, we estimated the mass and spin of M82 X–1’s black hole using this model, essentially following the methodology in ref. 20.

The relativistic precession model analysis requires that the three quasi-periodic oscillations, the two high-frequency quasi-periodic oscillations and a low-frequency quasi-periodic oscillation, be observed simultaneously. This is however, not the case for M82 observations. Although the combined six-year RXTE/PCA data show the high-frequency quasi-periodic oscillation pair, individual XMM-Newton observations randomly dispersed over the same epoch as the RXTE monitoring have shown low-frequency quasi-periodic oscillations with frequencies in the range of 37–210 mHz (see table 2 of ref. 10 and ref. 23). Thus, we carried out the analysis for three separate quasi-periodic oscillation frequencies, the lowest and the highest values (37 and 210 mHz, respectively) and a mean quasi-periodic oscillation frequency (120 mHz). The dimensionless spin parameter is constrained to the range 0.06 < \(a < 0.31\), and the inferred radius, \(r\), in the disk is in the range 5.33 < \(r_{\text{in}}/\text{H} < 6.82\) (Fig. 2).
Extended Data Figure 1 | Sample RXTE/PCA light curves and power density spectra of M82. The 128 s X-ray (3–13 keV) light curves (a, c) and the corresponding power spectra (b, d) of M82. The corresponding observation IDs are shown in the top right of each panel. The light curves have a bin size of 1 s, and the power spectra have a frequency resolution of 0.125 Hz. The error bars in a and c represent the standard error of the mean.
Extended Data Figure 2 | Long-term X-ray (3–13 keV) light curves of three accreting supermassive black holes. These were extracted from the same time window as the M82 observations (2004 September 2 to 2005 April 30 and 2006 March 3 to 2009 December 30). Data from 3C 111, MKN 110 and 3C 273 are shown in a, b and c, respectively. The count rates are not corrected for background.
Extended Data Figure 3 | Average X-ray (3–13 keV) power spectra of three accreting supermassive black holes. Similar to the M82 analysis, these spectra were extracted by combining all the data (128 s data segments) shown in Extended Data Fig. 2. The Poisson noise level is equal to 2, and the 99.73% and 99.99% confidence contours are indicated by horizontal dotted lines. The two dashed vertical lines are drawn at 3.32 and 5.07 Hz. In all three cases, 3C 111 (a), MKN 110 (b) and 3C 273 (c), there are no significant power spectral features. The total PCA exposures used for these spectra were 630 ks (a), 738 ks (b) and 711 ks (c).
Extended Data Figure 4 | Long-term X-ray light curve and the average power density spectrum of a background sky field of RXTE/PCA. Similar to Extended Data Fig. 3, the 99.73% and 99.99% contours and the vertical lines at 3.32 and 5.07 Hz are indicated in the power density spectrum (b). Again, only observations coincident with M82 monitoring were used (2004 September 2 to 2005 April 30 and 2006 March 3 to 2009 December 30), and the total exposure time was 1,450 ks. The light curve (3–13 keV) is shown in (a). The background has coordinates of RA = 5.0°, dec. = −67.0°.

5.07 Hz Quasi-Periodic Oscillation

$^a$ The total (source plus background) count rate in the given energy range (a).
$^b$ Not corrected for the background (b).
$^c$ Background-corrected percentage r.m.s. amplitude (c) where corrected r.m.s. amplitude = (uncorrected r.m.s. amplitude) × (total count rate)/(source count rate). The source count rate is the total rate minus the background rate. We used 128 s data segments for this study.
